PHOTOGRAPHIC NEWS:

A WEEKLY RECORD

OF THE

PROGRESS OF PHOTOGRAPHY.

VOLUME XIX.

EDITED BY G. WHARTON SIMPSON, M.A., F.S.A.

Nulla recordanti lex est ingratia.—MAESTAS.

LONDON:
PRINTED AND PUBLISHED BY PIPER AND CARTER,
15 & 16, GOUGH SQUARE, FLEET STREET, E.C.

P. 1875.
THE Nineteenth Volume of the Photographic News, to which these after words will stand as Preface, is the record of the observation and experiment, the discussion of theory, and statement of practice, of a year of unusual activity in many departments of our young but rapidly progressive art. The Preface to a volume serves many varied purposes: sometimes it is necessary to affirm the very right of existence claimed by the book; often it affords opportunity of preparatory explanations; and occasionally it assumes the tone of apology for sins of omission or commission which the book may contain. Our Preface has none of these purposes. The pages which have been issued from week to week have, we hope, established their own raison d'etre, and furnished, in their progress, explanation or apology, if any were needed. We write a Preface, partly because it has become customary, and partly because it affords the Editor an opportunity of speaking to his readers in a somewhat less impersonal fashion than is common in the ordinary forms of journalism.

The completed Volume of the year eighteen hundred and seventy-five is in the hands of our readers, and it needs no comment from us. As regards the future we have no new programme to offer. Our work in the past will be our work in the future. We have aimed to record, with completeness, and, where possible, to initiate or stimulate, progress in every department of photography, and the branches of art and science associated with it. We have endeavoured to aid the research of experimentalists and investigators, and to chronicle the results of their labours; to give wide currency to the teachings of the experience of the ablest practical men; to clear away the difficulties of the student; to announce discoveries and collate facts bearing upon photography in cognate sciences; to enforce and aid art culture amongst photographers; to consider and discuss the social, industrial, and commercial phases of the art; to aid in the advancement, in short, of photography in its every phase as science, art, and commerce, and to consider the interests of those devoted to its practice, amateur or professional—these have been our general aims in the
past; these will constitute our purpose for the future. In saying that we believe we have been successful in the achievement of the ends in view in the past, we do not speak with undue boastfulness, because in doing so we only recognize the efficient services of the numerous adjutors who have aided our work: not simply the services of the gentlemen associated with us on the staff of the Photographic News, but the extensive and valued body of contributors and correspondents to whose experiment, observation, and suggestion photography owes so much. To these we gladly avail ourselves of the opportunity of offering thanks for the past; to these we confidently appeal for continued aid in the future.

Of our personal work we need say little, beyond offering the assurance that it shall not in the future fall short of the past. Much of our duty is that of gathering, winnowing, selecting, and garnering; occasionally it is devoted to investigation and experiment; frequently to examination, testing, and proving alleged improvements; often to advice, suggestion, and instruction. We bring to our work upwards of a quarter of a century's practical and experimental familiarity with photography, and a score of years' experience in photographic literature, as well as the keen interest in it which renders the duty a pleasure. With the abounding evidence of the approval of our continuously increasing circle of readers in the past, we can but promise, as the past has been, the future shall be; and, with this promise, we conclude, wishing to all our friends—contributors, correspondents, and readers—a happy and prosperous new year.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

THE COLD WEATHER AND PHOTOGRAPHY — RODWELL'S INVESTIGATIONS OF IODIDE OF SILVER.—MINOR APPLICATIONS OF PHOTOGRAPHY.

The Cold Weather and Photography.—Say what you will about the cold weather, it is, after all, not nearly so bad as the dull, foggy days of November, that try the photographer's negative films, his printing, and his temper. When you have a good covering of snow on the ground, it need not be so bright overhead to make the printing go on more readily, for if the illumination is not very penetrating, the light is bright and diffused, and any description of cliché may be safely put out for printing. One important matter may always be borne in mind in cold weather, a matter first made known, we believe, by Mr. England, and subsequently confirmed by Lieut. Chermside during his photographic experiences in the Arctic regions. It is this: that one need not be under any apprehension even if the wet collodion film should freeze while in the dark slide, and ice crystals be formed on the surface of the negative image. During Mr. England's operations in America and Canada, the film of his wet plate, he has told us, would often freeze in the low temperature, for a long time would sometimes elapse between the plate's withdrawal from the bath and its development. At first he was much exercised in mind, lest no picture should be developed from the glazed collodion surface he brought out of the dark slide, but by his enemy, and directed it, the result was precisely as if nothing had happened. The result was in every way satisfactory, and there was no doubt, indeed, in the image to show that anything extraordinary had happened to the plate. Lieut. Chermside tells us the same tale. Frequently his wet plates froze during exposure, but this did not in any way militate against the result. The only difficulty we should experience about such plates would be as to the use of a warm developer. Thawing the ice crystals too rapidly would, no doubt, be injurious to the image, and the best plan, probably, would be to use a cold developer first and a warm one afterwards. The advantages of a warm developer in cold weather must be patent to all who have used it, and instantaneous pictures may be produced almost as readily in winter as in summer by this means. The collodion negatives shall not have developed in a third of the time as when the liquid is poured on almost freezing, and one need scarcely say that to the operator himself the employment of the developer in this condition is all the more pleasant. Should photographers have an objection, however, to their plates freezing in the rigorous weather we are now experiencing, there is a very simple plan for preventing such a state of things. Glycine, which is sometimes employed in the art of preserving the film during extremely hot weather, may be used effectually for the purpose in winter, for glycine, be it known, is a liquid which will only freeze at a very low temperature. Indeed, pure glycine would absolutely refuse to do so in a temperature such as we experience in this country, and it has the effect, when added to water or to aqueous solutions, of imparting to the same a retarding effect as regards their proneness to become solid in cold weather. We need say little on the subject of keeping solutions in working order during the wintry months, for photographers know very well that it is only by maintaining their baths and solutions at a moderate temperature, by artificial warmth, that they can do their work satisfactorily. Otherwise the baths work slowly, and the plates betray a general lack of sensitiveness and absence of vigour. However, as we said at the outset, bright, cold weather is in any case far preferable to the photographer than warm, foggy days; and he is generally by no means adverse to a sharp frost and a fine fall of snow, if his negatives are well packed, for not only can he get on with his printing, but there are some nice pictures to be taken on the lawn and in the shrubbery when the delicate twigs of the silver, birch sparkle with frosty rime, and the fir trees appear like petrified fountains overflowing with frozen foam.

Rodwell's Investigations of Iodide of Silver.—We observe that Mr. G. F. Rodwell has been reading a paper, at the Royal Society, on the subject of iodide of silver. He has nothing to say about this compound, so interesting to photographers, in regard to its sensitiveness to light, but, nevertheless, he brings forward circumstances which deserve, at any rate, a passing notice. He believes that iodide of silver exists in three allotropic forms. At a temperature of 116° C. and above it is a plastic, tenacious, amorphous substance, possessing a reddish colour and transparent to light. Below this temperature, and in the condition, therefore, in which photographers employ it, it is brittle, opaque, greenish grey, and crystalline. It may assume yet a third state, and that is when it is fused and poured into cold water; in this condition it is amorphous, and, of a greenish yellow, and it is in this form that Rodwell tells us, possesses its maximum density at or about 116° C., at the moment before it passes from the amorphous to the crystalline condition. The contraction and expansion of iodide of silver, when passing from one state to another at different temperatures, is said to be very marked indeed. It would have been interesting to know how the sensitiveness for light of the body is influenced by the changes of condition to which we have referred.

Minor Applications of Photography.—Among the many novelties which are prevalent just now in the shape of cards and pictures whereon to exchange the good wishes of the season, it is remarkable that there are none of a photographic character. Snowy landscapes and red-breasted robins are to be seen everywhere, but little winter sketches taken in the camera, which would be most apt and welcome if tastily mounted and finished, are nowhere to be purchased. This appears to us a most singular oversight on the part of photographic publishers, for there cannot be a doubt that the public would pay well for novelties of this kind, well executed, and the productions would be a pleasing change to the floridly coloured pictures which are now only to be bought. Many a photographer possesses half a dozen negatives of suitable subjects, but the size of the negatives, and the large sales which are effected in articles of this kind would assuredly make the matter a profitable one. Unfortunately this is only one of many instances where photographers are lacking in enterprise. There are many directions of a fancy nature, where photography could obtain a footing, if only photographers would make the attempt. For ball programmes, dinner cards, wedding certificate, for fancy mats, d'oyles, fire-screens, lamp shades, and a hundred and one other knickknacks, photography would come in most aptly, if only applied with taste and skill, and a design successfully carried out would surely command a price, if on the score of novelty alone. Why, we have often wondered, has no one among our clever advertisers ever thought of sensitising post-cards, incrusting upon them some photographic design or picture? The Post Office would be bound to accept them, as it would printing of any other description. What a field there is here for an enterprising advertiser, for, after all, the cost of such an enterprise would not be very much, when we bear in mind the costly advertisements that are sent through the post nowadays. It is the custom throughout France to send one's address card to friends on New-Year's Day, and the fashion has been adopted with some extent of late years. Should it become general what would be more a propos than to have the portrait of the sender neatly mounted in one corner? Christmas an
THE PRACTICAL PRINTER IN AMERICA.

CHAPTER XV.

VIGNETTE CAMEO AND MEDALLION VIGNETTE CAMEO PRINTING.

To print these beautiful styles a negative should be made expressly for them, having an ordinary size figure, somewhat smaller than the "Berlin head."

To print in cameo, the same idea holds good as in printing medallions, &c.; i.e., to show sufficient of the body to balance the head, but very little more. A ring is described below, and called a "cameo ring," should be stuck to the negative that is to be vignetted by the extreme corners, as if you were to print it in the ordinary medallion style, and after placing the sensitive paper on it the negative is then ready to be vignetted.

In choosing the vignette-block or in making the cameo box, with a view to the fact that a much smaller one is needed than if it were to be printed in the ordinary medallion, and consequently pick out such a one as will show enough of the body to balance the head and no more, although we might, if we were not printing this style, choose a block that would blend the print out to the very edges.

The reason why this should be heedful is because the finished vignette print, when pressed by the cameo press, ought not to have any of the halo show beyond the pressed-out surface, if you wish a very fine effect, as is the case, and the ring being placed on the negative prevents the halo from printing out further than where the ring is placed, and since this ring is made from the cameo press itself, it will, of course, when carefully pressed by it, give us the effect we wished for, viz., all of the printed paper is pressed forward while the white border retires. It is almost needless to state that the halo should blend out quite softly, both in the dressings and elsewhere, so that there will not: be a harsh appearance in the print, on account of its being stopped abruptly; hence the need of a small but deep printing-board and a piece or two of tissue-paper (according to its quality) for blending it.

In making the medallion vignette cameo, proceed as above, with the exception in the above case that whereas the print is finished as regards the printing when it is removed from the board, in this case there is to be an outside or border printed in, which may be of a variety of shades, as circumstances may permit. In making the cameo ring, place the die of the cameo press on a glass with the paper that you are to make cut-out of placed under it, and then with a sharp knife cut a quick and clean cut all around the inside of the guide.

In using the cameo ring, proceed as if you were printing his ordinary medallion, and in shading the outside, bear in mind to use the right mask for the cut-out used in printing the prints. (See Medallion and Arch-top Printing.) If the background is very light, the border should either be lighter or darker, but never of the same shade.

When the prints made are medallion cameo, and are not printed in the vignette, then the background is darker than what it would be if vignetted, and consequently the border cannot be printed lighter than the background; but when it is very often the case in printing the prints in vignette, the background is very light, then the border is generally printed until it bronzes, so as to give it a decided contrast: this produces an effect quite pleasing.

ON THE PRACTICE AND PRINCIPLES OF THE GREAT PORTRAIT PAINTERS.

BY A. R. ALDRIDGE.*

If I had proposed only some seven or eight years since to read to a body of photographers a paper on the practice and principles of the great portrait painters, it might have been asked, and with little show of reason, "What have we to do with the practice of artists, whether great or small?" When photography first started into existence but little more than thirty years ago, it was a something between chemistry and conjuring; and even now among the vulgar, who are ignorant of the means by which its effects are produced, it has still much of its ancient character. The great improvement in the character of photography, and especially of English photography, is generally ascribed to the exhibition of the works of Adam-Salomon, in the year 1877 As many of you have never had an opportunity of seeing these, our friend, Mr. Simpson, to whom we are indebted for their original exhibition, has kindly promised to show some of them to-night.

As photography progressed, one discovery following upon another not only proved the practicability of the new art, but pointed to a not very distant future when it might proudly take its place by the side of the sister arts of painting and sculpture; or, as some of its votaries thought, displace them altogether. This rivalry with painting, and especially with portrait painting, naturally conferred an upward feeling upon artists of the portrait art, many of whom, and especially the weaker or younger members, like Othello, found their "occupation gone," hence the origin of that apparent opposition between what are called the fine arts and this their younger sister—greatly, as I believe, to the detriment of both. Upon the whole, it is surprising that photography and painting, working side by side for so many years, have yet exercised so little influence upon each other. The artist still goes on making the studies for his pictures in thole laborious way, apparently ignorant or careless of the assistance photography might afford him, while the photographs of the present time, although still much in advance of those exhibited some few years since, yet appear (with some splendid exceptions) still wanting in those art qualities that raise the work of our hands from a dull copy of the commonplace in nature to what is in the best sense of the word we understand by a "picture."

If it may be allowed the expression, too many of our photographers appear to be wanting in brains. The author has been content to allow the lens to think for him. That huge Cyclopian eye sees things in many respects differently from the way in which they are presented to our double vision; much more does it differ from the eye of an artist. In the
first place, our friend is colour-blind; it cannot distinguish yellow from black, or blue from white. Then it is utterly wanting in discrimination; it dwells upon the buttons on your coat, the pattern of your trousers, or the wrinkles in your boots, and depicts them all with the same mechanical exactness with which it shows the lines of thought in the face of the sage or the smile on the lips of beauty.

"If you want to find out the faults of your picture," said Benjamin West, "set a student to copy it; he is sure to find and exaggerate them." It is the same with the lens. With what remorseless severity it seeks out and displays those freckles almost invisible to the naked eye! How it turns the rosy cheeks of youth and health to blackness and blueness, stealing at the same time all force or expression from the eyes that are inclined to blue or grey! Truly a blind leader for the blind! What has been said with respect to fire may be applied to the photographic lens—"it is a good servant, but a very bad master." It requires to be studied, to be humoured, and often to be corrected. And here it is that the artist-photographer has the advantage over his less enlightened brothers. Knowing well what can be done by the lens, he uses it to the best effect, but when the lens may afford him, but strives by the disposition of his background, by casting the light upon one part or sinking another in shade, by skillfully disposing his draperies and accessories so as to form graceful lines, to reduce what was before a chaos to order and harmony. It is in the hope of affording some slight assistance in this direction that the following observations have been written.

And here I should like to bestow a few words of thanks on those masters of the photographic art who have so liberally contributed the results of their skill and experience to their less fortunate or more juvenile brethren. I think that we owe them a deep debt of gratitude, and I, for one, tender them my most hearty thanks. As it is chiefly the purpose of the present paper to establish a few of those art principles that may be most useful in our practice, I shall say no more upon the historical part of the question than may be necessary to a right understanding of their practice.

Portrait painting, as we understand it, was but little practised by the ancients. The Greeks, who excelled as artists all other nations, whether of ancient or modern times, when they wished to transmit their counterfeit presentiment to posterity, generally preferred the more enduring marble or bronze of the sculptor for the purpose. We are told, however, that Alexander the Great sat to Apelles, the great artist of antiquity, for a full-length portrait. As the Emperor had something to do, but with his eyes, the painter turned his eye to the wall. I suppose that it is scarcely necessary for me to commend this piece of ancient practice to your attention. Alexander certainly approved, for he presented the painter with a sum equal to about 200,000 of our money. It is also of Apelles, if I remember, that another story is told. Having exhibited a picture, exception was taken by a shoemaker to the way in which the sandal was bid; the painter altered it. This so elated the critic that he began to find fault with the anatomy of the foot. "Let the cobble stick to his last!" exclaimed the indignant artist—a saying that has since passed into a proverb. It is recorded of another Greek artist that, having printed a picture in which some accessories (dead game, I believe) were greatly praised, he immediately retouched one thing, unwilling that they should distract the attention from the principal object. This was true art. It may be safely said that, whether in a painting or photograph, if any secondary object draw away the attention from the principal, it had better be left out altogether. The Romans never excelled, either as painters or sculptors. All their great works were either carried off from Greece, or executed for them by Greek artists. (To be continued.)

DRY PROCESSES.

BY M. A. DAVANNE.*

It is easy enough to work with the wet collodion processes in the studio, where one has room for placing baths and utensils conveniently to hand, but it is different when you have to photograph in the open air. Although a number of tents and portable laboratories have been from time to time devised, these form bulky and heavy baggage to drag about with you, and consequently photographers have of late turned their attention to the preparation of dry plates, producing sensitive films at home which may be carried a distance.

The different methods of preparing dry plates are very numerous, but we will only take notice of those which are most practised, and which give the best results. They are, in our opinion, the colloidio-albumen, or Tapanot process; the tannin process; the waxed paper process; almost obsolete at the present day. In all these processes, the point of departure is the same, viz., to obtain a film of iodide or bromide of silver in a permeable and insoluble medium; but what varies is the nature of the medium, or the preparation which is dried, the excess of nitrate of silver concentrates, and reacts upon the insoluble salts of silver, forming crystals of iodide or nitrate of silver, completely spoiling, therefore, the prepared surface. Moreover, the nitrate of silver reacts upon the organic matter of the sensitive film, and, altering it, renders the development of a good result impossible. It is necessary to employ it as a first condition, to wash the prepared plate to remove the excess of nitrate of silver, and the consequence is an immediate diminution of sensitiveness. For this reason, the dry processes are slightly less sensitive than the wet collodion process, although considerable progress has recently been made in this matter.

As a second condition, it is necessary to maintain the permeability of the film, and for this reason one cannot employ the ordinary collodion film simply washed, or, on drying, it loses its spongy texture, and becomes transformed into pellicle impermeable to liquids; for this reason it gives a superficial image only, without any vigour, because none of the reagents can penetrate the thickness of the sensitive film. A very old collodion, containing a trace of a pulp obtained from the cotton plant, gives a more open film, more permeable to reagents, and permitting of being employed dry, after simple washing; but as a result even in this case is always inferior to those obtained by the processes we are about to describe.

The general principle in preparing dry plates is to leave in the pores of the collodion a soluble and permeable substance, which may, on development, be replaced or saturated by liquid reagents. The number of substances that may be used for the purpose appears unlimited: gum-like, gelatinous, albuminous, saccharine, and dulciferous bodies may be used with more or less success, as long as they have no secondary action upon the sensitive film; thus beer, milk, wines charged with tannin, syrup, sugar, glucose, tea, coffee, tannin, gallic and pyrogallous acids, albumen, gelatine, caseine, deliquescent salts, &c., have all been tried; and from numberless essays it would seem that the best results have been obtained with albuminous substances, of which the white of egg is the type, and with bodies containing astrangent principle analogous to tannin, like tannin itself, the gallic and pyrogallous acids, tea, coffee, &c.

The Tapanot, or Colloidio-albumen Process.—The preparation of colloidio-albumen plates is rather a lengthy and difficult process, but its difficulties are compensated for by the constancy of the results, and the clarity and vigour of the results obtained.

After the glass plates have been cleaned with the greatest
care, a preliminary coating of very dilute albumen, previously filtered, is applied to the surface. The albumen is poured on like collodion, but if it will not flow regularly, a few cubic centimetres of ammonia are added, rendering it alkaline. It is necessary in this operation, as in all those that follow, to prevent contamination from dust with the greatest care. After the albumen is applied, the plate is put to dry upon a glass drain, and then put away into a grooved box until wanted.

Any good collodion may be applied; but if it is to escape work to be undertaken, then it is well to add a larger proportion of bromide (say 0.25 or 0.50 of bromide of platinum) for every 100 cubic centimetres of iodised collodion. The colloidised plate is sensitized in a seven per cent. nitric acid solution, which should be freely acidulated by eight or ten drops of nitric acid for every hundred cubic centimetres of the bath.

After immersion for three or four minutes, the plate is washed in distilled water in three successive baths, and then covered with iodised albumen prepared in the manner following:

White of egg ...... 100 cub. cents.
Glacial acetic acid ...... 1 cub. cent.
Water ...... 10 cub. cents.

Stir the mixture gently until it is well mixed, let it remain for a few hours, then decant the clear portion, and pour it through a filter, or a bit of sponge, or a tuft of cotton wool, so as properly to wash it. In this way a very limpid albumen is rapidly obtained.

Take of the above albumen ...... 100 cub. cents.
Iodide of ammonium ...... 1 gramme
Bromide of ammonium ...... 0.50
White sugar ...... 2 grammes

If the rooms in which you are working are a little damp, then it is necessary to place the glass with double the amount of a mixture of dextrine diluted with a little water

This solution of iodised albumen is filtered through paper several times, if necessary, to obtain a liquid perfectly limpid. Upon the sensitized plate, well washed and drained, there is poured, upon the upper portion of it, a band of this prepared albumen. This is extended over the whole surface by gently inclining the plate, and, after the liquid has dried, to move two or three times over the colloidation film, it is drained off. The plate is allowed to dry in a vertical position, sheltered from dust. The albumen solution may, at a pinch, be used a second time; but it is well not to resort to such an economical proceeding.

When in contact with the soluble iodide contained in albumen, the plate loses all sensitiveness; it may be exposed to light without inconvenience, and all the operations above described may, therefore, be conducted in a well-lighted chamber. The dry plate, when finished, should present an opaline and brilliant appearance.

If put into a grooved box well sheltered from the light, the prepared plates may be kept for an indefinite period. Before they are put away, a cloth, or moistened paper, should be passed over the backs, to remove any impurities which may have dried on the reverse side of the plates.

The sensitizing of the plates is conducted in orange or yellow light, by immersing the plates rapidly and at one motion in a bath of aceto-nitrate of silver. It is made up as follows:

Distilled water ...... 100 cub. cents.
Crystallized nitrate of silver ...... 7 grammes
Glacial acetic acid ...... 7 cub. cents.

The plate is allowed to remain in this bath, without being disturbed, for thirty seconds, and is then withdrawn by the dipper, and washed with much care successively in three baths of distilled water; the plates are finally rinsed under a fine stream of water, and allowed to dry. Thus prepared the plates may be employed within forty-eight hours. If it is desired that they should preserve their sensitiveness for an indefinite period (two or three months, or even more), it is necessary, after rinsing, to flood the plate twice successively with a half per cent solution of gallic acid, or even a saturated solution, and allow the film to dry. It is necessary to be careful, in dealing with this last named substance, that the fingers, if soiled with gallic acid, do not touch other plates during the sensitizing or washing operations. For this reason it is well to have two operators engaged on the work.

The exposure of these plates is, as we have previously explained, very variable, according to the instruments used, the nature of the objects, and the illumination at the time. In ordinary landscape views the exposure generally from one to six minutes; in dry processes, however, a very great latitude in the duration of pose may be given, the errors of exposure being compensated for by a greater or less length development, and by adding more or less silver to the developing solution. If the plates have not been treated with the gallic preservative, the development should follow within a few hours of the exposure. Generally, the development commences of itself, and the image is in part visible before one begins to apply the solution. The developing solution is prepared of:

Water ...... 1000 cub. cents.
Gallic acid ...... 8 grammes.
Pyrogallic acid ...... 3
Glacial acetic acid ...... 15

If the weather is cold, enough of the developer for a plate is warmed to a temperature of 30° or 40° Cent., although this precaution is unnecessary in mild weather. For every hundred cubic centimetres of the liquid there is added two cub. cents. of a three per cent. solution of silver; this mixture is excited, and the solution put into a bath in which the plate is contained. The development is conducted gradually, and it is necessary to agitate continually to prevent the formation of black spots, which are produced whenever the developer is allowed to remain undisturbed upon the plate. The best plate is to put the necessary quantity of liquid into a clean glass dish, which is slightly tilted, and, having placed the plate at each corner of the plate, to put this face downwards into the solution. The development then goes on very regularly, and the face of the plate is prevented from touching the bottom of the dish because of the points of sealing-wax.

The coming of the image should be carefully watched. If it appears too hard, from under-exposure, the proportion of nitrate of silver is diminished, and the dose of developer augmented. If, on the other hand, the image appears too uniform, then the extra quantity of nitrate of silver is added to make the contrast more marked. As soon as the image appears sufficiently developed (which happens after a lapse of time varying from ten minutes to several hours), it is washed under a current of water, and fixed in a twenty per cent. solution of hypoosmophite of soda.

As the fixing takes place upon a film which is but slightly impermeable, the operation is longer than in the case of wet collodion plates. By looking at the plate by transmitted light the fixation of the film is easily watched. Finally, the plate is, of course, well washed. As the film is hard, and not easily injured, it is possible to print, without risk, a copy, first of all, before varnishing, so that some idea may be gained of the vigour of the image, and, if necessary, the cliches may be intensified further, adding a little more acetic acid to the developer in the first place.
Recent Patents.

PHOTO-ENGRAVING AND BLOCK PRINTING.

By J. H. Banks.

The following specification describes a method of producing photo-intaglio plates, such as are used in copper plate printing, and photo-relievo plates, such as are used in typographic surface printing:

The object of my invention is mainly to produce from a drawing upon paper or letterpress, copper plate, or lithographic print or drawing, a raised surface block applicable for typographic surface printing, or a plate similar to an engraved copper or steel plate applicable for printing by the ordinary copper plate or lithographic press; the raised surface plates can be produced either flat, or they may be cylindrical, for the purpose of printing upon cloth or paper, as requires, metal dies to be used as seals, or for stamping paper, or paper like material, as shown below, or to be used as embossing plates for bookbinders for stamping or embossing book covers or leather, or other substances in high relief, or for other purposes connected with the printing, bookbinding, or packing, or embossing trades where printing or embossing is used.

To produce the above results, either from a drawing, letter-press print, photograph, or any work of art on paper or painting, I first obtain a photographic negative in the ordinary way upon gelatine film or paper, and then coat the camera upon glass (No. 1), except that I lastly develop it with a solution of bichloride of mercury, wash this off with cold water, and then put iodide of potassium, wash this off with cold water, and then put hydrosulphuret of ammonia, say, to two ounces, one gallon, for the purpose of making the whole plates in the print or drawing as opaque and black as possible on the glass, so that the sun or artificial light used in printing the design upon the prepared glass No. 2 (which I hereafter describe) shall not act upon the white spaces of the picture. I then make a glass No. 3, by laying it perfectly flat, and, according to the quality of the lines or work on the design, so make the thickness or thinness of the film of gelatine or chondrine, which I prepare as follows:—take two ounces of gelatine, chondrine, say, one ounce of Zimmer's or Frey's size, mix it with about twice the weight of the buffalo, or from parchments cuttings, and cut it into small shreds, and then pour upon it one pint and a half of cold water, and let it stand until it is dissolved, say about ten hours, and then gently make it hot, not to boil or burn, and after laying the glass of flat on the film of six inches by ten inches, three ounces, and then leave it to dry; after it is dry I then make up in a bath a solution composed of one ounce of bichromate of potash, or other bichromate or peroxide of chromium, to one quart of cold water, and heat it to a freedom of steam, and then place the glass containing the dried gelatine film upon it into the bath, baking the mixture covers it entirely, and when it has remained in three or four minutes I then take the glass out of the water and put it on its ends to drain and dry, taking care that no driblet of water enters the room, only gas or dark yellow light when this prepared glass No. 2 is perfectly dry and the film hard I then take an ordinary pressure frame with a plate glass front, and on the plate glass I lay the photographic negative glass No. 1, then the silvered side upwards, and upon this side I place a piece of black velvet upon the back of glass No. 2, press the whole tightly together, and expose the glass to the sun's rays or to magnesium, electro-magnetic, or other white light for about five, ten, twenty, and then get printed impression—this is the design upon the negative glass being transparent, and the white parts being black. The sun or other light can only go through the transparent parts, and so converts the printed portion of the gelatine into an almost insoluble compound, leaving the white parts perfectly soluble, take it into the darkened room, and having prepared a bath containing one ounce of bichromate or peroxide of chromium, mixed with chloride of sodium one ounce, and by brushing the gelatine with a brush all the white portions wash away, and the design is left on the glass standing up untouched. I then immerse it in this bath for two minutes, and having prepared and afterwards take from it a plaster cast, from which a second plaster cast can be taken, and printing surfaces be prepared from it as herein after described.

The mode, however, which I prefer, is, instead of using hot water, to use cold water, one quart mixed with ten grains of iodine or sixteen grains of iodide of potassium from a quarter to half an hour, then take it out and put it into a bath of cold water mixed with twenty drops of ammonia for a quarter of an hour, then take it out and place it in a bath of two quarts of cold water mixed with one ounce of acetic acid for about five or ten minutes, to harden the edges of the design that have not been raised up. By this means I obtain a gelatine surface mounted on having the white portions of the drawing raised up to a very great height—quite as high as any wood engraving is cut in depth, and the drawing is level and sunk; the gelatine surface has also been strengthened and toughened, so that a cast can afterwards readily be taken from it, whereas heretofore the cast from gelatine plates have been very imperfect. I then mix some plaster of Paris or cement, and take a cast which gives the design raised up and the white portions indented, similar to wood engraving. Should any of the white portions not be sufficiently deep, I then proceed to deepen them. I then roll over the raised portions of the plaster cast a mixture of printing ink and copal, or some one of the varnishes now in use commercially, and when dry I dip the plaster mould into a bath of very weak soap one part, and cold water five hundred parts, and brush it with a soft brush, and while it is under water I harden the plaster with weak alum and pyrogallic acid and water until the air bubbles cease to rise from it. Another way I have to cut away with a gouge all the whites that are not sufficiently deep enough; but if I require to take a casting in plaster of Paris, I then do not use alum but use the plaster mould by immersing it in a bath of hot size, a little treacle, and peroxide of chromium, until the air bubbles cease to rise from it, and then expose it to light; and while wet I lay a frame upon it, pour in the plaster of Paris, and just before it sets I put it under some wood, and the loose water being pressed out gives a much sharper casting.

If an electotype is required instead of a stereotype casting, I then take the plaster cast that has been taken from the gelatine film, and soak it in cold water, until bubbles cease to rise from it; then with the face of the plaster cast I then print upon it by using mercury. By washing the mould with spirits of wine, and, when nearly dry, allowing the fumes of mercury to settle on the face, I get a metallic covering which readily receives a surface of copper without being brushed, whereby the fine lines are kept intact.

I then take a glass plate similar to a copper plate engraving, I take a negative with the lights and shades reversed, and by adopting the same portion of the process of glass 1 and 2 which relates to the printed representation on glass No. 2, and raising the surface with acetic acid only, I then take a plaster mould, and by the use of the electotype and electrotypes I produce an ordinary engraved copper plate with the drawing indented, exactly similar to an engraved plate which can be printed by the ordinary copper plate press. For some work I modify the mode by not taking a negative, but by placing the print in contact with a print on glass No. 2, and proceeding as already described, a plate is produced which can be printed from in the ordinary manner.

Having thus described the nature of my invention, and the manner of performing the same, I claim, as my invention, in the production of printing surfaces and of engraved metal surfaces applicable for other purposes,—1. The combined process substantially as herein described for the production of raised surfaces applicable for typo printing and other uses. The combined process substantially as herein described for the production of engraved plates applicable for copper plate printing and other uses. The use of a bath of bichromate of potash or other bichromate or peroxide of chromium with hydrom of lime added to it for sensitizing the gelatine plate. I also claim a modification of the process of setting, when taking plaster casts from gelatine plates or cast plates from them, as herein described. 7. Imparting a thin film of mercury to the surface of the gelatine plate, or wax impressions, by the means herein described to prepare them for electrotyping.
PHOTOGRAPHY IN 1874.

A brief glance at the photographic history of the year should be instructive as well as interesting. It is important to ascertain what actual progress has been made, what practical gains are available to the photographer, and to what extent they have been adopted in general practice. Photography has undoubtedly been active during the year, and some progress has been made; but no specific or important discovery distinguishes the annals of the year just past. The advancement of an art is, however, frequently as dependant upon improvement in a multitude of minor matters, as upon actual discovery, and in many cases, more important detail photography has been undoubtedly progressive.

The wet colliodion process remains practically unchanged, and without the prospect of important change. The preparation of colliodion having in this country gradually left more and more in the hands of commercial makers, there is little temptation to experiment with varied samples, and the various commercial kinds possessing almost all desired qualities, amongst them, change is scarcely desired or desirable. The negative bath inevitably exercises the photographer continually; but whilst various modes of treating its ingredients are proposed from time to time, no radical change in its constitution has been adopted. There has been a growing tendency to work the silver solution in a neutral condition, and a proposal by Mr. F. Elmer to use it in a slightly alkaline condition, employing a colored sample of colliodion, is well worthy of attention, as promising immunity from many troubles. The developing solutions employed remain as usual, a diminishing tendency to much intensification being general.

Portrait photography has not undergone much change. The production of pictures with a large proportion of shadow, or half shadow, especially on the face, which has been difficult, has become more general. The use of gelatin and colliodion to produce what is termed an enamel surface, with or without the "cameo" treatment, has also prevailed during the year. Large portrait has also been more prevalent, an especial impetus in that direction having been given to portraiture by the prise munificently offered by Mr. Crawshay. The production of enlargements has also received considerable attention, and among the most extensively employed is the use of enlarged negatives obtained by the aid of fine textureless positives on albumen or carbon tissue having largely superseded enlargement on paper, with or without development. Mr. Crompton's method of producing an enlarged transparency, admitting of modification by means of the pencil, as an aid to the production of a perfect enlarged negative, is also successfully practised. A method of enlargement which has received much favour in Paris has been patented by M. Lambert. It consists in producing an enlarged negative from a carbon transparency. The negative so produced is thin and delicate, like a glass positive, all the intensity being derived from a subsequent process of retouching, which is effected by working on transparent paper, covering thin negatives on both sides. To skilled hands the process is easy and rapid, and the results very successful.

Dry plate photography has received much attention during the year, and has made some progress, especially in modes of development. The strong alkaline developer introduced by Colonel Stuart Wortley has been extensively adopted, and is found very valuable when other processes besides the usual bromide process, to which it was originally applied. Emulsion processes have received much attention and some improvement. A method of preparing the colloidio-bromide of silver without excess of the haloid salt, or of nitrate of silver, by precipitating the solid portions of the emulsion, washing, and re-dissolving in ether and alcohol, promises much success. Rapid plates, emulsion and otherwise, have been introduced with much success in commerce. Gelatine promises to acquire an important position in dry plate work, considerable progress having been made in preparing emulsions. Mr. Kennett has introduced a dry sensitive gelatine pellicle into commerce, which simply requires solution in water to render it fit for use. Some discussion has arisen on the patent acquired for this preparation, the chief point of importance to the photographer being found in the fact that the pellicle itself promises to be successful, negatives of great excellence and an unusual degree of rapidity being attainable by its use.

The use of diffused light as a means of reducing camera exposures has received considerable attention during the year. The use of such a device is well worthy of attention, as the result of extended experience. The use of coloured light, which has been held by some careful investigators to possess an occult value, has been generally abandoned. The most general and successful method of applying light consists in exposing the sensitive plate, whilst in the camera, to diffused white light, modified and softened by placing a piece of opaline glass (or some other material) in front of the lens for a few seconds prior to exposing the sitter. A general agreement amongst those who have tried it in portraiture prevails as to the fact that it gives harmonious pictures with short exposures.

The discovery announced by Dr. Vogel at the close of last year as to the property acquired by films of bromide of silver, when treated with certain colours, of becoming sensitive to the usually non-acetic solar rays, has been the subject of some experiment and much discussion during the year. The result has been that the discovery—at first much questioned—has been, on further experiment in various hands, confirmed and accepted. Its practical applications, it is probable, may be found valuable.

Printing processes have received considerable attention during the year, but the modification of ammonium sulphate of silver has been effected. Modes of eliminating the remaining traces of hypo sulphite from the print after washing have been much discussed, but nothing distinctly novel has been introduced. The use of acetate of lead has received considerable discussion, the general tendency of opinion amongst those who have tested the question being in favour of its use. The use of a strong solution of ammonium sulphate of silver has been proposed in America, and highly approved by experienced men. Its operation appears to be analogous to that of sulphuric acid, proposed in our pages by Charles Martel many years ago; but its use is probably attended with less danger, although it is doubtful whether the print will escape the risks attendant on the decomposition of the hypo sulphite in the manner proposed. The
THE PHOTOGRAPHIC NEWS.

precise and careful application of known modes of fixing and washing appears as yet to furnish the surest safeguards against change in the print.

Carbon printing has improved, but has not, probably, extended much in general application. Methods of photo-mechanical printing have acquired more precision in the hands of those who have devoted attention to their development, photo-collodion processes having attained a high degree of perfection. A more extended and general commercial application of press photography is also manifest.

One of the important features of the year is the general introduction of the powder process of reproducing negatives. The principle, which is many years old in its application to the production of enamels and carbon prints, was first employed as a means of reproducing a negative, direct from a negative, without any intermediate stage, a few years ago; but did not acquire general attention. Early in the past year, in a paper read before the Vienna Photographic Society, Herr Oberritter stated that he had successfully used it for reproducing thousands of negatives of large size. The subject rapidly excited attention, and has been successfully applied. Various modifications of the process are described, and it is used as a means of modifying ordinary negatives either in intensity, or by introducing new pictorial features, as proposed by Mr. Werge. The new powers it places in the hands of the photographer will probably prove very valuable.

An important feature in the photographic history of the year is the power the art has placed in the hands of astro-nomers in recording important phenomena. Its application in the Transit of Venus has had a degree of success which has transcended the hopes entertained. Perfect success has attended the photographic operations of various observing expeditions in different parts of the world, and the results are sufficiently valuable to suggest the possibility that photography may supersede other modes of observing similar phenomena. It is worthy of remark, that from the most successful photographic results, are those of Captain Abney, who relied on the use of dry plates and strong alkaline development.

Photographic societies have been active during the year, and some new societies have been established which promise to be successful. A serious schism arose in the Photographic Society of London at the close of last year, which at one time threatened the destruction of the Society. The controversy continued for about six months, accompanied with much bitter discussion, subsided; some slight modification in the laws of the Society, and a considerably weakened cohesion amongst its members, being the chief issue of the strife. The ostensible origin of the disension was a desire for a revision of the laws of the Society, and as the existing authorities expressed a perfect willingness to aid in such revision, it is inexplicable, on looking back, how such a disruption could have arisen. All the officers having resigned, they were, with one or two exceptions, re-elected to office by a plebiscitum, a modified code of laws was passed, and, with a view to render the Society more comprehensive in its aims, the name was changed from the Photographic Society of London to the Photographic Society of Great Britain. If the general spirit of unanimity and co-operation at present apparent continue to prevail, it is possible that the Society may recover its former stability and usefulness. The South London Society continues especially prosperous and active, and is acquiring a metropolitan rather than a suburban character, in the important technical exhibition it holds towards the close of the year, to which a large number of photographers from all parts flock for information.

The exhibition of the Photographic Society, held some what under difficulties, was successful, although, perhaps, scarcely in the progressive ratio of former years. A fine collection of excellent photographs from all parts was shown for information.

printed in carbon, exhibited by the Autotype Company. A finer display of large pictures of a permanent character was never exhibited. Not less in interest, and more varied in character, was the noble array of large direct pictures and enlargements competing for the prizes offered by Mr. Crawshay. A fine display of landscapes, also, competing for similar prizes, was not so transcendentally excellent as the temptation might have elicited.

The balance at the close of the year suggests the conclusion that photographers might, with advantage, endeavour to break new ground, or carry research more ardently into some channels which have already been indicated by former pioneers. The salts of silver still form the basis of general photographic operations. The use of bichromate of potash has, of late years, been steadily extending in connection with permanent and mechanical processes; but here the practical applications of the art stop. The salts of iron, uranium, and various substances which have given promise of photographic value in years gone by, receive but little attention. We have seen some admirable prints in various colours, of the permanency of which there was little reasonable doubt, produced during the year by Dr. Diamond, by various modifications of the Verneuil process, and by the use of potassium played important parts. Dr. Schimna has developed images on iodide of mercury during the year. M. Saint Floureth, M. Ducos du Hauron, and M. Vidal, have given attention during the year to polychromic photography by different methods; but the number of investigators in untrodden fields is too few, and the concord and co-operation is insufficiently general, to secure rapidly the valuable results which might arise from more systematic and more united research.

VENDING SECRET PROCESSES.

There are few subjects upon which the Editor of a photographic journal is more frequently requested to give an opinion than on the value of various secret processes offered to members of the fraternity "for a consideration." As a rule, it must be obvious that he cannot with propriety give any opinion whatever. The business of a photographic journal is to give publicity to everything he can learn in connection with the art, and he generally avoids receiving information to which he cannot, in virtue of pledges of secrecy or considerations of good faith, give the publicity of his pages. Hence journalism and secrecy are antagonistic. It must, however, be admitted that the modus operandi of the vendor very often goes something to the effect of the fee he charges; not always because he sells a secret, or something which has never before been published, but because, out of many methods of effecting a given end, he has, after careful proving, selected and verified the best, saving to the busy professional photographer the task and time of searching and verifying for himself. Valuable forms are often passed over unnoticed by readers of journals, until some startling evidence of their value is thrust upon their attention. The powder process for reproducing negatives and for modifying negatives had been published some years, but few photographers had given it attention, and fewer still had tried it, until Herr Oberritter announced last year that he had successfully reproduced some thousands of negatives by it, and verified his statement by the exhibition of results at the Vienna Exhibition. A skilful process-vendor might, no doubt, twelve months ago have honestly obtained many fees for teaching the process, which is one of real value. Without entering further into the question of secret processes and the policy of purchasing them, we commend to the attention of our readers a brief communication on another page, by Mr. Young, of Llandudno, whose excellent work in the last exhibition will remember. Mr. Young's subject is analogous to that made in our pages some months ago. He urges upon photographers interested in the progress of
THE PHOTOGRAPHIC NEWS.
[January 1, 1875.]

THE EFFECTS OF LIGHT AND HEAT ON IODIDE OF SILVER.

An interesting paper on the effects of heat on iodide of silver, and incidentally of the effects of light, was recently read before the Royal Society, by Mr. G. F. Rodwell, F.C.S., F.R.A.S., some abstracts from which will prove very interesting to photographers. The paper commences by a quotation from Professor Clerk Maxwell, to the effect that iodide of silver is the only solid body which is an exception to the general rule that heat expands bodies, and further cites a remark by M. Fisean, stating that this body offers an example of the complete inversion of an ordinary law, as its volume very decidedly diminishes when subject to heat, and expands when made cold. Water and fusible metal (bismuth) are of course well known to expand under the influence of cold, but in both these cases a change of state is simultaneously effected, whilst no such change occurred in the case of iodide of silver. In proceeding to his work for testing this point, Mr. Rodwell obtained examples of iodide of silver by different methods:—(1) By precipitation. Pure iodide of potassium was added to nitrate of silver, both in dilute solution. The precipitated iodide was thoroughly washed in the dark, slowly dried, fused in a porcelain crucible, and cast into cylindrical masses, either in a warm porcelain or brass mould. (2) By dissolving pure silver in strong hydriodic acid, and evaporating the resulting solution of pure silver leaf for several hours to the vapour of iodide produced by spontaneous evaporation.

Before examining the effects of heat upon the iodide, Mr. Rodwell thinks it may be well to say a word or two concerning the action of light upon it, as a considerable amount of misconception appears to exist in regard to this fact; and in verification of his statement, he cites the opinion of various authorities. Omelin says "it turns brown on exposure to light, but less quickly than the chloride;" Miller says "it is but slowly acted upon by light;" Fisean describes it as "noirissant lentement à la lumière;" while Vogel ("Jahresbericht," 1863) affirms that it is precipitated with excess of iodide of potassium it is scarcely affected by light, whereas if precipitated with excess of nitrate of silver it changes color, but undergoes no chemical change. In the general idea, the author adds, "that it is nearly as sensitive to light as the chloride, has no doubt arisen from the fact that iodides and chlorides are known to have many points of resemblance, and that the iodide is largely used in photography; moreover, we remember that a thin film of iodide of silver was the sensitive medium in the original Daguerreotype. But we must bear in mind that the change produced by light is not apparent until the so-called "developer" is applied, the silver being reduced to the metallic state, and forming an opaque metallic film on the parts of the surface which have been exposed to light."

The following were the experiments made by Mr. Rodwell to determine the degree of sensitiveness of the iodide to light:—

a. By means of a large lens the rays of the electric lamp were brought to a focus within a glass cell containing a solution of iodide of potassium; a solution of nitrate of silver was then introduced by a pipette at the apex of the cone of rays. The precipitated iodide possessed its usual pale yellow colour.

b. Freshly precipitated iodide in suspension, with a slight excess of nitrate of potassium, remained in the full glare of a July sun without undergoing any perceptible change; neither did it subsequently darken.

c. Freshly precipitated iodide in suspension, with a slight excess of nitrate of silver, underwent no immediate change on exposure to a July sun. At the end of an hour it became slightly grey, and subsequently darkened.

d. Organic matter in the form of starch paste did not induce any change when mixed with freshly precipitated iodide in suspension with a slight excess of iodide of potassium. Albumenised paper with iodide precipitated upon it did not undergo any immediate change.

e. Some dried and powdered iodide was found to have acquired a slight greyish metallic tinge after an hour's exposure to the sun. A freshly broken surface of fused iodide became very slightly darker after exposure to the sun. A very pale microscopical crystal of iodide, removed from the interior of a crystalline mass, became slightly brown after several hours' exposure to diffused light.

f. Crystals of iodide of silver produced by direct solution of silver in hydriodic acid were not affected by light; neither were crystals of hydro-sulphate iodide (AgI2), nor crystals of argento-potassic iodide (AgI).

g. A sheet of silver leaf was exposed to the vapour of iodide (produced by spontaneous evaporation) for five minutes; it possessed a faintly yellow tinge, which on exposure to the sun instantly became pale green, but on further exposure returned to its original pale yellow. A second sheet was exposed for ten minutes to the vapour of iodide; it acquired a golden-yellow tinge. A third sheet exposed to diffused light acquired a purplish-red colour, and on exposure to the sun became greenish purple. On continued exposure this colour disappeared, and the plate returned to almost the original yellow colour.

h. A sheet of silver leaf was exposed to the vapour of iodine for half an hour, at the end of which it possessed a decided golden yellow colour; on exposure to the sun it instantly acquired a dark purple colour, edged with green in those parts least exposed to the direct vapour of the iodine. On continued exposure the purple became paler, but the sheet did not return to its original yellow colour.

i. A developing solution composed of ferrous sulphate, alcohol, acetic acid, and water, when applied to the exposed sheets of g and h, which had been purple, but on continued exposure nearly regained their original colours, produced a reddish-brown colour.

j. A sheet of silver leaf was exposed to the vapour of iodine for many hours; it was found to be converted into a slightly coherent film of lemon-yellow iodide. Light had no effect upon it, even after long exposure to a July sun; neither was any colour produced on the addition of a developing solution.

The pure iodide of silver would thus appear to be scarcely affected by light, except when silver is present, either in the form of nitrate, or, as in the case of the silver films, as metallic silver.

We shall return to the effects of heat on the iodide in our next.

FRENCH CORRESPONDENCE.

Despite the incontestable advantages of glass clichés, it is well known that for some time past, substitutes have been proposed to obviate many of the inconveniences that this heavy and fragile substance possesses. Several photographers have made use of other vehicles for the collodion, and M. Silvy is one of those who have gone back to the use of waxed paper. One of my correspondents, M. Quiquet, has recently communicated an idea on the subject, which merits at least to be seriously considered.
He takes a pellicle of collodion similar to that employed in carbon printing. This is moistened in a bath of alcohol, and then washed with distilled or rain water. The pellicle is then carefully pressed in a blotting pad, after which it is floated upon a brome-iodized albumen bath. The latter may be rendered more adhesive by the addition of some suitable substance.

After demeciation, the albumenized sheet is floated for a few seconds upon a bath of acetate-nitrate of silver, and afterwards again washed with rain water, as in the case of waxed paper. After removing the excess of liquid by pressing between blotting paper, the sheet, while still moist, is attached by the margins to a sheet of cardboard, as is the case with the dry papers of M. Marion. In this way the sheet is stretched out in a most perfect manner, and it is then exposed in the usual way in the camera. The image is developed either by means of gallic or pyrogallic acid, or even with the aid of an alkaline developer.

In this way we secure a cliché which has, besides the quality of transparency, the triple advantage of not occupying any space, of being extremely light and not fragile, and which, moreover, may be printed from the true or reversed side without trouble. The important point is to determine whether the film of collodion and albumen is sufficient to resist the different operations which the film has to undergo.

It is probable that these pellicles may be preserved for a long time after they have been sensitized, by covering them with a tannin preservative, or with the gallo-albumen compound in the same manner as dry plates are prepared.

The Academy of Sciences received at its last meeting a communication respecting which I must say a few words. It was upon the subject of the action of hydrogen upon nitrate of silver in solution. This action has already been the subject of study on the part of MM. Merget, Rousset, Pellet, and others. Both M. Rousset and M. Pellet have obtained some conflicting results, for while the first declares that hydrogen reduces silver in solution, the second states that the gas has no action whatever. M. Pellet attributes the reduction observed by M. Rousset to a trace of arsenic in the hydrogen employed, or to an excess of oxide of silver in the nitrate.

M. Békétoff, the author of the article to which I refer, has employed in his experiments the quantitative method; and so as to be able to measure with accuracy the amount of silver reduced, and hydrogen absorbed, he allows the experiments to continue for a long time, the action of the hydrogen being excessively slow in the experiments employed. The action of hydrogen was obtained by means of zinc which contained no arsenic; moreover, the gas was purified by passing through a tube containing pumice stone impregnated with a solution of nitrate of silver, prepared with re-crystallized salt from an acid liquor, and slightly dried. The solution of silver salt and the hydrogen were contained in sealed tubes enveloped in several sheets of paper which were clamped in a horizontal position in darkness. The results obtained and the exact figures are contained in a table joined to M. Békétoff’s communication, and prove that the reaction is a simple metallic displacement, and that for every molecule of silver salt reduced, there is an absorption of an equivalent quantity of hydrogen, and formation of free acid, which is proved, moreover, by the fact that after the experiments all the liquids are found to be alkaline.

The author concludes from these results that pure hydrogen reduces silver in the same manner as other metals in a neutral or slightly acid solution.

Just as the year is closing, it is well, perhaps, to cast a glance behind at the number of works that have been produced during the last twelve months. The period has been very prolific in France, and if we have not to record any absolutely original discovery, we have at any rate had the pleasure of making known numerous improvements in various phases of photographic art.

Thanks to the ingenious modifications in manipulation and retouching by M. Lambert, photographic enlargements have become more easy of production, and have attained also a degree of perfection which till now was denied them. The process, under the name of Lambert-type, is now carried on on such a large scale that it is within the reach of the humblest provincial photographer. Without the least aid from an artist, it is possible to produce prints enlarged, superior to those obtained by other methods at a great expense.

Next to Lambert-type comes the “Reflectoscope” of M. Van Tenac, which allows one to produce a copy direct from a carte-de-visite without having to go through a series of operations, as in the case of the old method. Moreover, sunlight is not necessary for the purpose, and a simple enlarging lamp is all that is required, so that in the evening, or in dull weather, the work may be continued without loss of time. This is an invention of great importance, the value of which will become more apparent every day.

The production of photographs in colour has also made marked progress during the present year. In the first place, the labours of Mr. Leon Vidal, whose polychromic images are well known, must be referred to as being very successful, as exemplified by the specimens recently presented to the French Photographic Society. Printing in colours has become such a practical matter under his hands that in a short time we may expect to find the method practised as a branch of industry. The experiments of M. Ducos du Hauron, confirmed in a most conclusive manner by the experiments of M. Geymet, lead us to hope also for the solution of the problem in a more scientific, and probably simpler, manner.

Photography in pigments has received this year more disciples than it ever possessed since the origin of the process. Already many photographic establishments have adopted this method of printing exclusively for their ordinary work, and if one is to believe the new works of M. Lambert, it may be safely asserted that carbon printing has definitely taken its place in the studio.

Photo-mechanical printing has also made some progress during the present year, and I may cite, among other instances to prove this, the journal called Paris-Theatre, which, instead of containing engravings of a more or less successful character, publishes every week portraits of theatrical celebrities printed by the Woodbury Process.

As to heliographic engraving, although the Rousselin process has remained since its publication in the hands of the inventor, and is solely worked by the well-known photomechanical printers, Goupil and Co., the process is none the less an accomplished fact in photography, and will doubtless before long be placed at the disposal of the world at large.

ERNST LACAN,

**ABSOLUTE ALCOHOL.**

**BY JOHN A. SPENCER.**

The preparation of absolute alcohol being attended with some difficulty, and the loss of product usually very considerable, a ready means of preparing it in moderate quantity may not be unwelcome.

The mode prescribed in the Pharmacopoeia to prepare absolute alcohol is to separate as much water as may be absorbed by a small quantity of subcarbonate of potash, to pour off the supernatant fluid from the oily solution formed on standing for a couple of days, on to about half its weight of quicklime, and then, after another rest of twenty-four hours or so, to distil it gently by means of a water bath. This yields a very good product, but it is expensive, as the difficulty of removing the latter portion of the spirit from the magnes of lime is very considerable.

The method I have adopted, and found successful, is the following:—Take about two pounds of subcarbonate of potash, and heat it to redness, or nearly so, in an open iron pan over a close fire, stirring it to prevent agglo-
meration of the particles. Then, having half a gallon of rectified spirit, 60° overproof, placed in a small still of copper or tin, put the potash salt by spoonfuls at a time, while still hot, though not incandescent, into the spirit, and immediately attach the head of the still, placing a cork in the extremity of the pipe and luting the junction. After allowing it to remain for a day or two, with occasional shaking, this with the aid of water will still spirit cease to pass over, when about three-fourths of the bulk of the original spirit will be obtained, having a sp. gr. of about 0.804, which, though not absolutely absolute, will contain close upon ninety-five per cent. by weight of absolute alcohol, strong enough for any purpose required for photography. It is well to reserve the first few ounces that pass over, as this is less strong than after the distillation has proceeded regularly. An advantage of this mode of preparation is that the residue in the still is not wasted, but may be put into an open pan and boiled down over an open fire till it has become dry, when it may be preserved in a well stoppered bottle for use on another occasion.

COMBINED EFFORT IN TESTING NEW PROCESSES.

BY J. M. YOUNG.

That oft-quoted "strange conservatism," which locks advances at everything new, and to which the fraternity must plead guilty, has unquestionably been the means of putting many a guinea into the pocket of the man with the "secret process." Were we working photographers to assign but a few days in each year to the testing of theories or the working out of practical suggestions, new or strange, the occupation of the secret vendor would be gone. But he it is that tests these theories, that works out their practice; and it is only when he brings us his results and shows us that there is really "something in it," that we are brought to look carefully and to say, "Good; I shall go in for that. How much, eh? Penalty. I don't like that idea." But like it or not, the document is generally signed, and the risk of no end of law business incurred, and the guinea paid. Brown, you see, on the other side of the street, will be sure to have it, if you don't; but what have you got for your money? Something, in nine cases out of ten, that you knew all about before; and you feel ever afterwards that you have a grievance. You declare war with every man with a secret process.

Why is this thus? Let each man answer for himself. Not long ago, I saw, in Paris, the slides and coloured negatives which have the credit of producing photographs in colours. There may be something in that. If fifty good men and true were to try, and then report results, something more might be made of it; and this is certainly one game that is worth the candle.

THE SIMPLE COPYING PROCESS.

BY OBSERVER.

A CORRESPONDENT of the English Mechanic states: "Blue leaf prints are obtained by floating paper on a strong solution of ferricyanide of potassium, commercially called the red prussiate of potash. They are fixed by simple washing." Here there is evidently some mistake, as, in order to obtain anything like satisfactory results, it will be found necessary to mix with the red prussiate about the same quantity of citrate of iron. With this solution impressions of the form and outline of any leaf, copies of writings, plans, and drawings in outline may be obtained—a clear, clean white on a blue ground—the printing to take place in direct sunlight.

To make the case plain for any one inclined to try the same, dissolve about two grains of the iron, and the same quantity of the red prussiate, in two ounces of water. Paste a piece of brown paper round the bottle, and keep the same out of the light. In using this mixture, the best papers for the purpose are Whatman's thin drawing for large subjects, and any good thick note for small ones. Papers of the thin order, or such as are deficient in sizing, do not yield good impressions. To coat the paper, use a large round camel hair brush. Place the paper on a piece of card or stout millboard, holding it firmly to the same by the thumb of the left hand; with the right hand dip the brush into the mixture, and, commencing at the top, lay on the mixture from left to right evenly and lightly, avoiding all streaks or dribblings at the edges of the paper, and in some place free from dust and out of the direct light to dry. Then place them between folds of blotting-paper to keep them flat, and use them without much delay.

To Prepare Subjects for COPYING.—This may be done on thin writing paper (afterwards oiled or waxed to make it transparent), ordinary tracing or clarified vellum tracing paper, or engineer's tracing cloth; horn paper or French vegetable may also be used. Care must be taken that the ink ticket-writers use for making the design, &c., is sufficiently opaque to stop out the light. To ensure this, when the subject intended for copying and printing is finished on one side of the transparent paper or medium, and quite dry, go carefully over it again on the other side, using ink or a good HB pencil. This will be found a necessary proceeding in order to obtain satisfactory results.

With respect to the printing, it must take place in direct sunlight. A photographic printing-frame may be used, or one of the transparent slabs sold at the stations: the only thing required is to remove the piece of ground glass, and insert in its place a piece of thick plain. A very little practice will enable a person to calculate the time of exposure from the tone of the paper. When the same has become a dull dirty grey, with the subject scarcely perceptible, it is then time to remove it from the frame and immerse it in clean water, allowing it to remain for ten minutes or a quarter of an hour. During this time a sort of gradual change will take place, the dirty grey coming out a pure bright blue, with the subject in clear, clean white lines. After washing for a few minutes in any convenient place to dry, when it may be placed under a weight to press it flat, and considered fixed and finished.

If the process be not of any trade value to photographers in general, there are a large number of students, authors, antiquarians, artists, engineers, geologists, surveyors, and others who may find the same of considerable use and service; and many will already have seen their descriptions may execute various effective presentable subjects in moonlight and snow pieces, together with illustrated cards and designs on note paper, which, if not of any direct commercial value, will be found of interest to many from the simple and inexpensive way in which they can be produced and multiplied.

Some examples of inscribed stones, wayside crosses, ancient doorways, monuments, and a curious copy (the same size as the original) on lead, "The Absolution of Godfried," Bishop of Chichester, are sent to show the capability of the process from an antiquarian point.

PHOTO-ELECTRIC ENGRAVING.

BY JOSEPH LEOPOLD.*

Director of the National Engraving and Photo-Electric Engraving Institute at Liezen.

I do not propose to speak of much that is new on the present occasion, but, as the title of my paper indicates, I am going to discuss a subject already twenty years old, but which, despite its age, and the fate of the inventors and his process, has not yet become strong and matured, but is still in its infancy.

When Paul Pretsch, in 1854, had brought his invention in the Vienna State Printing Office so far that he had confidence enough to bring it before a larger public, he chose

* Photographische Correspondenz.
London as the place where he would bring out his invention and—make his fortune. In a few weeks after his arrival in that city, he found himself supported by several early acquaintances, who interested themselves in his invention, and formed a company to work out the process with an artistic, as also commercial, finish. The choice, which of Pretsch brought him and his invention speedily forward, and by hard work and industry he was enabled, in a very short time, to supply many successful results by his process, which not only in England, but on all sides, were the attraction and admiration of experienced men.

The members of the company, however, without knowledge of the affair, or of its artistic and commercial value, were, like all others, seized with the speculations of the time. The energy of Pretsch was still too new and impractical to satisfy would-be shareholders, the ideas and hopes of the inventor were not realised. The process of Paul Pretsch thereupon lost its importance in England; it was neglected, and soon quite forgotten. Pretsch exerted himself still, and produced some good results; but his good fortune had forsaken him, and, despite his energy and skilful invention, his results were powerless to ensure him success in a foreign land.

It is not my object to depict the misery which the brave and intelligent man suffered, and with which he wrestled for many years previous to his death in order to secure his daily bread. My purpose is rather to revive the interest which the invention of our countryman awakened, so that, after eighteen years of silence and oblivion, we may carefully study the nature of the process, and, as it is the true worth. Some months ago, as a friend of the deceased, I already found myself morally compelled to grasp the pen in striving to prevent the matter from becoming altogether a thing of the past.

Paul Pretsch has, so far as I know, attracted and left behind no other disciple than Duncan Dallas. This gentleman has published only incomplete details of his method of working, and, therefore, for myself I went to work on the subject, and undertake manifold experiments, to make myself acquainted with the operations. In these I employed the well-known principles laid down by Pretsch, by means of which, aided by the experience I already possessed of similar processes, I was enabled in a short time to secure successful results as the fruits of my pains.

The advice and assistance of many friends in the matter I have to acknowledge most heartily, especially those of Dr. Emil Hornig.

The process which I shall endeavour to explain, so far as my experiments teach me, and of which I am happy to lay before the Vienna Photographic Society some fruits, is closely allied to the art of engraving. It would receive useful application in every establishment where illustrated publications are produced, and where, at the present time, a large amount of money is expended in costly drawings and engravings by hand.

The process is as follows:—Paul Pretsch employed (as I do myself) in producing a block for copper-plate printing, an original photographic positive on glass. The production of such a positive and transparent cliché from a negative requires a little special knowledge and experience. Everybody, however, who is conversant with the preparation of photographic clichés, would soon become as well in the matter. The operator must take especial care that the picture is uniformly developed and intensified in its shadows and half-shadows. To secure the brilliant qualities of a good cliché to the picture, the deepest shadows must have sufficient transparency, so that the picture, without too long an exposure, can be vigorously transferred to the photographic film in every part. As support for the photographic process, good white glass should be carefully chosen, which must, moreover, be very flat. The basis for the photographic substance is another glass plate, which must possess the same qualities. It is easy to understand that the choice of the plate often controls the later success of the work.

The invention of the process employed, as we know, for the composition of his photogenic film, glue, bichromate of potassium, nitrate of silver, and iodide of potassium. The proportions of the different substances I have set fast after many experiments. I take

| I. | 16 grammes of glue (best) | ... | 3 fluid oz. water... |
| II. | 2 " | bichromate of potassium | ... | 1 " |
| III. | 1 " | nitrate of silver | ... | 1 " |
| IV. | 4 " | iodide of potassium | ... | 1 " |
| V. | 8 drops of vinegar, which are added after the other substances have been dissolved and mixed together. |

The glue is allowed to swell for some hours beforehand in the allotted quantity of water. As I carefully calculated the proportion of the crystallised substances in proportion to the glue, I lay particular stress upon the calculation of the amount of water for the same, and no tedious failures should take place.

The glue is dissolved in a water bath, as are II., III., and IV., to which a portion of the warm solution of glue is added. Then III. and II. are mixed together, being thoroughly stirred the while, giving rise to a dark reddish colour. On the addition of IV., iodide of silver is formed, and for this reason the dark becomes lighter. To this mixture I added 8 drops of glacial acetic acid, and then I filtered the whole through a double fold of linen.

This filtered solution is poured upon glass plates, which are dried in an oven in a perfectly horizontal position, the liquid being applied warm upon the warmed plates, a glass rod being used to facilitate the spreading of the mixture. The addition of glacial acetic acid aids in the uniform spreading of the film, and the grain formed is thereby rendered of a finer character. The temperature of the oven should never be very high. A steady heat of 32° Reaumur suffices to dry the plates in a period of from three and a half or four hours.

(To be continued.)

Correspondence.

SHORTENING THE EXPOSURE.

Dear Sir,—Allow me to recommend all those who are interested in this matter to try the simple expedient proposed some time back in the News. It is to remove the stop when the exposure is half over. Thus, suppose it is found that with a certain lens a medium sized stop is required in order to secure the requisite definition, and that the exposure necessary would be one minute. Instead of exposing full time, at the end of a quarter of a minute remove the stop, continue the exposure at full aperture for another fifteen seconds, and cap the lens. This is just half time. Try a plate both ways, and judge the result.

At first sight it seems likely that the removal of the stop would produce some defect in the image: one carefully-made trial will show how groundless is such a fear. The diaphragm must fit the slit easily, of course, and a little drill will make its removal an easy enough affair. In taking large-sized heads and portraits on 18 by 16 plates I have been convinced of the great practical value of this suggestion.

Edward Viles.

Penrhyll Hall.

Talk in the Studio.

WAYMOUTH'S VIGNETTING MASKS.—Mr. Waymouth has just issued a little pamphlet giving some good hints as to the best mode of employing his useful masks, and citing a large number of favourable opinions as to their efficiency.

PHOTO-BLOCK PRINTING.—The very excellent process of superimposing at an ordinary printing press, with blocks produced by photography, and known as Dallastyle, is, we understand, about to be offered to photographers to purchase by subscription; the precise details will no doubt be duly
announced. Mr. Dallas is, we understand, engaged in producing a reduced fac-simile of the original folio edition of Shakspeare, and copies of it will be sent from there in the British Museum. The Dallas edition will, we believe, be in royal octavo, and issued in parts.

**RESTORING FADED NEGATIVES.**—Mr. Colquhoun, of Alexandria, sends the following:—Having noticed several times correspondents recommending a yellow negative as giving good results, I fear these have been got up as with me—that is, with iodide of mercury (bichloride of mercury and iodide of potash)—they will fade away through time; at least, I have lost two in this way, and in looking over I can see one or two more on the way. The varnish has been removed by alcohol from carbonated ether, and re-introduced with the iron developer and a few drops of silver from the negative bath, and the yellow appearance is changed into something like stone, having more the appearance of a collection negative without treatment. Enclosed is a print before (No. 1), and another after (No. 2); the latter, neither deep printed, perhaps, but it shows that the thing can be done.

**CYANIDE POISONING.**—A deplorable case of poisoning recently occurred in the family of a photographer in Loches, Scotland. The photographer, Mr. Kenneth, had recently removed from Dundee, and some of the chemicals contained in his box had been placed in a gatherers' wagon. The driver of the wagon, Mrs. Kenneth was emptying the pail of its contents to put them in a safe place, and a child of three years was playing beside her at the time. The mother turned back for a minute, and the child just took off the pail a vial containing cyanide of potassium. The child, being of a nervous constitution, drew the cork, and swallowed its contents. The father, who was in bed at the time, saw the child almost in the act, but too late to save it. He immediately ran with the child to Dr. Alexander, who gave it an emetic, but it was of no use, the child having died in the course of twenty minutes from the time it took the poison. The Procurator-Fiscal is making the usual examination. Great sympathy is expressed for Kenneth and his wife under this sore trial.

**ACTING ACTION THROUGH WATER.**—The Atheneum says:—"It has been determined by M. Forœl that the chemical action of the sun's rays in summer causes, in the Lake of Geneva, at the depth of between forty and fifty metres. The depth to which the chemical rays penetrate in water has never before been determined. M. Forœl has communicated his researches in a memoir to the Société Vaudoise des Sciences Naturelles.

**PHOTOGRAPHY.**—The Art Journal says:—"Mr. James Hughes, Jr., and a very young and very able collection of photographers, have sent us several photographs of dogs. They are admirably executed, partly, perhaps, because of the purity of the atmosphere, but owing much to the skill and judgment of the artist, who has studied the "sitters" carefully, and with valuable results. They supply material for any painter, and so numerous and varied as to include almost every class and order of the animal that is emphatically the friend of man. Mr. Hughes does not give us merely their portraits: sometimes he represents them as exhibiting the tricks and winning ways that endeared their companionship. An album full of these pictures will be a rare acquisition to the drawing-room and boudoir of the lover who loves the dog, but not to others; the lover of field and aquatic sports may see the likeness of his favourite, and the lady a copy of her lady's favourite. A more agreeable collection of photographs "from the life" has never been submitted to us."

**TRANSIT OF VENUS.**—The following telegram has been received at the Royal Observatory, Greenwich, from Professor Petros, via Wellington, New Zealand:—"Transit observation great success first contact. Photographs, two hundred thirty-seven." Lord Lindsay has also been successful.

**US CORRESPONDENTS.**

**E. MATTHEWS.**—There is no work published in this country devoted to retouching. There was a small book of a few pages devoted to the subject published some years ago in America, but the book is not now to be had in the Photographic News. You will find many books devoted to the subject in our last half-dozen volumes, and forthcoming and recent Year-Books.

**NIGRO.**—It is impossible to say what is the precise cause of fuming. It is a fact that the air may be, as you suppose, the fault of the nitrate of silver but it may be the fault of the collection, or of the developer, or of something else. If you have strong reason to believe it is the fault of the developer, by adding a little more nitric acid, one may get a sample of collection. Should you find the addition of more nitric acid insufficient, try boiling again; but neutralise this with care, use a little arsenate of soda, or a little caustic potash, instead of arsenious. We do not approve of this, because it is not a negative result, but for this reason: when nitric acid is added to remove alkali, nitrate of ammonia is formed, and, as the salt will hold on to its alkali, in solution, when you add nitric acid, the reaction is little suspected. Cold weather and bad light are, of course, inimical to successful photography. You should keep the dark-room and solutions up to a temperature of at least 60°, or from that to 80°, i.e., in order to secure good work, allow full exposure.

**F. R. B.**—We have an indefinite recollection of having seen such a lens many years ago; but do not remember by whom it was made except that it was a French maker.

**G. D. F.**—You not state by what process you wish to work on optical glass, whether by developed camera printing or the use of collodion-chloride in the printing frame. By using collodion-chloride you will obtain the best results in several of our Year-Books. If you wish to produce an entire or diminished image, you must print in the camera in the same manner as you would in the dry process, but use a very strong neutral solution of chloride of g 11. The formula given in our pages a few years ago for working the bromium process answers well.

**B. O.**—Clippings from prints are generally worth saving for the sake of the negatives; many really printed clippings are, however, worth saving; white margins and the tramlines of vignettes should contain no silver at all.

**Tyr.**—You are fortunate in having had no experience with what is termed the "old hypo solution," as with such a solution produced by its aid remain permanent, its results were full of uncertainties. It was often a serious compound, consisting of hypo-sulphite of soda which has been used over and over again, and has left silver and chloride of silver and silver carbonate attached to its fixing as well as its toning powers, but careful workers generally save the print a few minutes in a fresh hypo solution after it left the mixture in question. We do not think that experiments in the same direction will repay your effort.

**A. B. C.**—You may not without permission copy the engravings in Punch, the Illustrated News, and similar works, either for the magic lantern, or any other purpose. The owners of these publications have a copyright in the engravings in question. You will find that gold toning is very useful for copies of prints for the lantern.

**R. E.**—The prints in question were not ressealed, but were mounted on the glass, which gave the singularly delicate and transparent effect to which you refer. You will find details of the method in our forthcoming Year-Book.

**S. J. ROCHAMBEAU.**—Pyrogallic acid in the ordinary sense of the word, and does not, like acids, form salts. Certain combinations with pyrogallic acid in some bases have been produced, and termed pyrogallics, but not many. We have experimented extensively in that direction, and did, we believe, form a pyrogallate of soda, but we do not remember the formula he employed. Pyrogallic acid easily undergoes decomposition in the presence of alkalies. We should recommend you to apply to some practical chemists, such as Hopkins and Williams, to supply you with what you require.

**PHOTO. MECHANIC.**—There are various modes of blocking the brass-work of lenses; but the full wire is the best and four drachmas of bichloride of platinum and one grain of nitrate of silver, and dissolve in six ounces of water. Make the brass-work with silver, and apply a little black varnish on the back. When dark enough, wash the surface dry, and polish with black-lead.

**DICK.**—The chief objection to a studio with south light arises from the fact that it involves constant change of blinds and curtains, and constant uncertainties, as direct sunlight enters the studio during a great part of the day, whilst a north light is of much more uniform character. If you make up your mind to the inconvenient labour and expense of solving, you may by care and skill get some very fine effects indeed.

**G. E. R.**—The best mode of increasing the body of your collodion is to use a little more nitric acid in the developer, but apply a little pyrogallic acid, which you may obtain of most stock dealers.

**DRET PLATE.**—Almost any dry plate process may be used in producing transparencies, but the Ceisse process is one of the simplest and most successful, but apply a little pyrogallic acid, which will be sufficient exposure. Develop with pyrogallic and silver.

Several Correspondents in our next.
The Photographic News, January 8, 1875.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

PHOTOGRAPHY AND THE POLICE.—A NEW MECHANICAL PROCESS—IMPROVEMENTS IN COLLOID PRINTING.

Photography and the Police.—We cannot help thinking that far too little use is made of photography by the Home Office—or, more correctly speaking, perhaps, the police—in matters that come under their notice and supervision. Only the other day the correspondent of the Daily News, in commenting upon the diurnal occurrent at Shipton, lamented that the victims of the catastrophe had not been photographed immediately after the affair, as during the time that elapsed in some cases before identification of the bodies their faces had altered materially. The countenances, we are told, were in the first place placid, calm, and even pleasant to look at, but after a while the features changed very much for the worse, and not only were the poor remains very horrible to gaze upon, but they had also lost a good deal of their character by means of which the identification would be made. The operation of photographing would, therefore, have saved much pain and anxiety to those coming to inspect the bodies, for these need never have been shown at all, unless the portrait of the deceased gave something of the deceased being the person sought for. It would have been very awkward indeed to have a large set of prints and distributed them to the police stations of the country towns about England, where friends might see them; or the pictures might be sent on application to relatives at a distance for identification, so that these might not be compelled to undertake a long journey that might turn out fruitless. There are many other directions in which the police might make useful applications of this art, beyond the mere taking of portraits of prisoners which is already the only use made of photography by our guardians of the peace. Photographs of articles lost, missing, or found, if posted in frequented thoroughfares, would materially assist in their being restored to their rightful owners. It would not, surely, be too much to ask that a camera might find a place among the many other requisites of large police stations.

A New Mechanical Process.—A new process, called the Auwäldrudk, is announced in the German papers, of which M. Aubel, of Cologne, is the inventor. No details are given of what it is, but some information is afforded to us of what it is not. It has nothing, we are told, in common with Woodburytype, Albertype, or photo-lithography; it does not necessitate the use of the galvanic process, nor that of calotype. It is said to be gelatine, gum, asphalt, etc., neither is any transfer method made use of. The original negative is said to be transformed direct into a printing block, as hard as steel, from which any kind of engraving or lithograph may be produced. The rapidity with which reproductions may be secured by its means is proved by the fact that a picture was copied and many hundred fac-similes distributed in a couple of days. The process is adapted to fast work, and will print matter which can only be read by means of a magnifier. From what we hear we should think the process is only calculated to produce pictures in black and white, or copies of matter in type, and the results are no doubt similar to those of the photo-electric method of Duncan Dallas, whose charming little reproductions of the Pall Mall Gazette and Fun will be well known to many of our readers. Whether the results are better or worse than these is anyone's own affair.

Improvements in Colloid Printing.—It is very certain that a great stride has recently been made in photo-colla type printing, or Lithodruck, Albertype, or by whatever name it is called. Till within the last few months ordinary photographic portraits have not been satisfactorily produced from a gelatine block, and the Woodburytype has been the only trustworthy process by means of which any portrait negative of small dimensions has been made to yield prints at all comparable with silver photographs. Now and then, it is true, we have seen Lithodruck or Albertype cartes-de-visite which approached very nearly to silver prints in delicacy and gradation, but these were from negatives specially chosen for their peculiar adaptability to the process, and of ladies in light dress and without costume, and the costume and felt wide awake. There were no heavy shadows or dark draperies, for as soon as a bit of black velvet or a startling contrast was attempted by the collodion process, a defective place inevitably appeared. In reproducing the finer portions of a picture, in depicting lawnwork and the more delicate portions of a dress, the process was eminently suited, but the heavier costume and background, such as might be secured by a combination of practice and good fortune, but are really due to honest straightforward work. If it should really turn out to be the case that photographs in printer's ink of a perfectly permanent character can be produced equal in appearance to the less stable silver impressions, then we have here to record a mighty step in photographic art in a month or a day. But it will not do for the collotype prints to be nearly equal to ordinary photographs in appearance; they must be quite as favourable to the eye, otherwise the public will not have them, despite their great degree of permanence. The introduction of such work would work something of a revolution in the photographer's work, for it is scarcely to be anticipated that he will be able to print his own negatives. Let the collodion printing be simple as possible, and the prints will only be obtainable by very skilful and practised manipulation, and it will be quite one man's work to do this and nothing else. A photographer will have to confine himself to taking and retouching negatives, and send them out to be printed by those who make collodion printing their special study, for only in very large studios would it pay to employ skilful artisans constantly at the work. That portraits in this way will no doubt be an expensive matter where a small number of copies only are required, but when it is a question of even two or three dozen, there will be a saving in having recourse to mechanical printing.

ON THE PRACTICE AND PRINCIPLES OF THE GREAT PORTRAIT PAINTERS.

BY A. R. ALDREDD.*

We pass, then, to more modern times—to that gradual revival of the arts which took place in Europe during the middle ages. During the fourteenth and fifteenth centuries painting, both in Italy and Germany, was especially in the former, gradually emerged from the cloud of Gothic darkness that had long obscured the taste, design, and genius of art. In the sixteenth century painting in Italy attained a height of glory and perfection unknown in any previous age or other clime, and which has been the envy and admiration of all succeeding times. We are now on firmer ground. The artists have long since returned to their kindred clay, but their genius still survives in their works. Early in the sixteenth century painters lived together, or about the same time, those great masters whose names have become "familiar as household words" wherever taste and genius are appreciated. To quote the names of Leonardo da Vinci, Raphael, Michael Angelo, Corregio, and Titian is, at once to conjure up in the mind of the artist or connoisseur the remembrance of those great representative men who, while giving to the art some grace or beauty unknown before, each in his turn impressed upon it the
peculiar stamp of his own genius. They were all great inventors, and not one of them on his own peculiar ground has ever been equalled. Da Vinci, the earliest of these artists, in addition to his reputation as a painter, was also noted for his skill in sculpture, engineering, and mathematics. He has left many works on arts of works; and his "Treatise on Painting," which has been translated into many languages, it still one of those books most read by artists. The picture he is now most noted for is the celebrated "Lord's Supper," where the Saviour is seated at the table in the midst of his disciples. There is a small picture of Christ disputing with the doctors in our National Gallery.

Da Vinci, Raphael, and Michael Angelo all excelled in form. Da Vinci gave to the human figure a roundness and grace unknown before. He also greatly improved the chiaroscuro, or light and dark. His pictures are finished with extreme care, and the shadows have a particularly lucid effect. Raphael has often been called the "prince of painters," as he is allowed to unite more of the higher qualities of the art than any other. His drawing is from nature, mastered, and his draperies flowing and graceful. He is allowed to excel all others in expression and in the beauty of his female figures. It fortunately happens that we have in this country, and accessible to all, some of his noblest works. I refer to the famous cartoons now at South Kensington. Raphael did not paint many portraits, but there is one by him in the National Gallery of one of his pupils. He was the sculptor of David and Moses, and the architector of St. Peter's, at Rome. Michael Angelo did not paint in oil, and never painted portraits; he must, therefore, be dismissed without further comment. Correggio, the next on our list, was particularly noted for grace; the softness and depth of his chiaroscuro, the art of using light and shade, and the breadth of his imagination, are not to be found in any other artist. He was also the architect of St. Peter's, at Rome.

Michael Angelo excelled in the sublime and terrible. If Raphael be the Shakespeare, then Michael Angelo may be styled the Milton, or, still better, the Dante of painting. He had the extraordinary fortune to attain to be the first place in three kinds of arts. As a painter, he produced the "Last Judgment," which is generally allowed to be the sublimest picture of modern times. As a sculptor, he is famous for his figures of "David" and "Moses," both of which may be seen in the Museum at South Kensington. He was also the architect of St. Peter's, at Rome.

There are three of his pictures in our National Gallery, all of the finest quality—the "Ecce Homo," the "Venus and Cupid," and the charming little "Holy Family," a perfect gem.

The last of those I have mentioned is Titian, the great head of the Venetian school, and acknowledged to be the greatest oil painter of his day. While his subjects are of the most brilliant and brilliant colours through his historical works, till they seem all aglow, should yet, in his portraits, and especially in his male heads, generally exclude all strong colour. The accessories—always simple in Titian—although of the noblest character, are subdued; it is the head that fixes your attention. The figure, the costume, and the accessories are there, but they are not for them; they are there only for the sacrifice of the attention from the countenance of Titian. This is the more noticeable as the costume of the time was in those days of great elegance and dignified. So anxious, however, was Titian that nothing should divert the attention from the head, that he frequently covered the hands with a dark glove, in order not to have a second light in the picture. If you wish to see the only one, the names of Giorgione, Paul Veronese, Sebastian del Piombo, Tintoretto, Fordinone, Bassano, and others at once recall to the artist the heads full of glorious life—all faces of the most dignified type, and features of female loveliness, which, though wanting the refined and delicate beauty that Raphael or Correggio would have given them, yet smile from the canvas with all the glowing freshness of life and nature. The Venetian school, besides leading the way through the paths of art, displayed an acknowledged power and variety not reached by any other school of modern times.

The school of Spain has produced several artists of eminence, the principal of whom are Murillo (the Spanish Raphael) and Valesquez. Both these artists, in addition to their skill in the use of colour, are noted for their extreme freedom of handling, for power, freshness, and a general look of nature—not possessing the thoughtful dignity of Titian's heads or the refined elegance of those of Van Dyke, but startling by their vigour and truthfulness. There is only one portrait by this master in our National Gallery, that of Philip III, but his characteristic excellences are well displayed in that.

The Flemish and Dutch schools are principally eminent for works to which we commonly apply the name of "genre" pictures—generally subjects of a rustic nature or taken from everyday life. The painters of these schools are generally noted for excellence of colour, skill in chiaroscuro, and a love of picturesque and local effects. They reduced the principles of the Italian schools to a regular system, and it is to their works that the artist generally goes to learn the principles and mechanical practice of his art. The heads of this school are Rubens (the "prince of painters," as he is sometimes called by his numerous admirers in opposition to the more refined and classical style of Raphael) and his pupil Van Dyke. They are both noted for their grand manner, and their qualities of the art, were both great colourists, and painted pictures of the largest size, whether sacred, historical, landscape, or portrait. In the last, especially, they both excelled. The portraits of Rubens are painted with great force and freshness of colour. There is at Windsor Castle a room named after him the "Rubens Room," and filled with his works. There is also in the National Gallery a fine portrait of a woman in a straw hat, called the "Chapeau de Paille," from the collection of the late Sir Robert Peel.

What I have said respecting the portraits of Rubens applies generally to the similar works of his pupil, Sir Anthony Van Dyke. The latter, however, though generally having somewhat less force, are more graceful in their quality and character, and are Among these remarks of this artist:—"Happily the works of Van Dyke are not scarce in this country, and in them you will see admirable examples of what has been urged respecting the beautiful arrangement of light and colours united to all the graces of intelligence, mastery execution, and his style is much more correct and beautiful than that of Rubens."

The painting is full of life and nature, and the painter to whom I can do little more than add, although his works are of the very highest class—I mean Rembrandt. To give any sufficient idea of his works would require a paper in itself. The common idea among photographers respecting this great master is that he always turned his sitter's back to the window, and represented them with black faces having a streak of white running down the nose. Truly a comical idea of the painter! I suppose I must have seen 200 or 300 portraits by his hand,
but never happened to come across one of those straky Rembrandts. He was noted for the great force and brilliancy of his lights, which were generally obtained by concentrating the light (very often he has only one) upon one part, and surrounding it by masses of dark shadow, often bordering upon blackness, but never black. After these foreign masters, if such they be—for I hold with Voltaire, that "ceux qui aiment les arts sont tous con-citoyens" (those who love the arts are all fellow-citizens) in these days—never, we may very well devote a few lines to the portrait painters of our own school.

The greatest of these, undoubtedly, Sir Joshua Reynolds and Gainsborough, the latter of whom was equally noted for his skill and originality as a landscape painter. Sir Joshua Reynolds has been surpassed in his male heads, but his women arc, to my thinking, unqualified. There is about them a feeling of grace and beauty, united to a power and easy mastery in the execution that places them at the very head of their kind. I can only mention a few of the finest. Amongst these may be enumerated the picture of the three "Misses Waldegrave," the famous and charming "Nelly O'Brien," who is seated in a rich landscape with the shade of a tall hat thrown over the upper part of her body; the celebrated portrait of the "Devouche" holding up her child, his picture of "Mrs. Siddons" enthroned in the clouds as the tragic muse, and the picture of another great actor, "Garrick between Tragedy, Tragedy and Comedy." The pencil of Reynolds seems to have been all it touched. However vulgar or commonplace his sister might be, they always appear upon his canvas as ladies and gentlemen, and equally celebrated painters and boys of "Devouche" holding up his child, his picture of "Mrs. Siddons" enthroned in the clouds as the tragic muse, and the picture of another great actor, "Garrick between Tragedy, Tragedy and Comedy." The pencil of Reynolds seems to have been all it touched. However vulgar or commonplace his sister might be, they always appear upon his canvas as ladies and gentlemen, and equally celebrated painters and boys of

Gainsborough is noted for the great force and freshness of his portraits, and the masterly ease of their execution. He studied Rembrandt and Vanderwyle with great success. There are three very fine examples of Gainsborough's portraits in the National Gallery,—"Dr. Schomberg," "Mrs. Siddons," and a masterly rendering of an ordinary head, called "The Irish Clerk." The limits of a paper like this will only allow me to mention the names of the remaining artists of the English school who have best succeeded in portraiture. They are Romney, Sir T. Lawrence, Jackson, and Raeburn, called the Scotch Valasques.

I will now endeavour to extract from the works of the great painters I have named some principles that may be of service to us as photographers. The first and most important principle that I wish to state is this: the whole of sacrifice. The parts must be sacrificed to the effect of the whole. If a number of objects strike the eye at the same time, and are possessed of equal force, they naturally compete with each other, and thus weaken the effect of the subject. The principle is thus expressed in Dufresney's "Art of Painting":

"...not all will succeed, but some will be the first to strike the eye..."

This is confirmed by a note of Sir J. Reynolds. As the head is the most important part of the portrait, so it should first attract the attention. In the best works of the best men the principal light always falls upon the face and, where necessary, all other parts are subdued so as to concentrate the attention upon it. Painters who work with much less light than is found convenient in photography always light the head from above, and it is held most conclusive to effect that the light should be small. Rembrandt—who is supposed to have derived his first ideas of the striking power of a ray of light in the midst of a mass of shade from the effects he had observed in the interior of his father's mill—has often carried this brilliant contrast to the extreme, so as to show scarcely anything but the head. Northmore, also, in describing the studio of Sir J. Reynolds, tells us that it was lighted by a single window eighteen inches square, the lowest part of which was about ten feet from the ground. Sir J. Reynolds, again, when speaking of the early painters who obtained relief for their heads by bringing the light part of the background against the dark part of the head, and vice versa, recommends the contrary practice of Titian, who often relieved the darks of his heads by a still darker ground, thus giving an appearance of great breadth. This plan is in advance of our present photographic practice.

One most important feature of the face is certainly the eye. All the masters I have mentioned succeeded in giving great expression to the eyes—the "windows of the soul"—while, unfortunately, in every large photographic head this has been the weak point. I do not remember one in which this important feature has been perfectly satisfactory. It is also of great importance in lighting the head to place it so that the eye shall be in shade, or at least in half-tint. The next important feature is the mouth. Generally the corners are turned slightly up, which gives a pleased and pleasant expression; if the corners of the mouth are drawn down the face is sure to wear a look of pain.

Thus much for the head, to which, as I have previously observed, it has been a rule among painters that the figure should be subordinated. How far this principle of sacrificing a part to the effect of the whole is to be carried must depend upon the taste of the artist, whether he be painter or photographer. Titian and Rembrandt in some of their works carried the idea so far that little besides the head is visible; while, on the other hand, Gainsborough, whose portraits have more the look of ordinary daylight, allows greater prominence to the figure. The principles I have laid down have been not much followed by photographers; still there are brilliant exceptions. I have observed, Adam-Salomon was one of the first to apply the recognized principles of art to photography..."
PHOTO-ELECTRIC ENGRAVING.—(concluded).

BY JOSEPH LEIPOLD.

The exposure of the dry sensitive film under the transparent positive must not take place immediately after the plate's withdrawal from the oven. The film, which is of a very sensitive nature, is put away for some hours in a dark place, so as to come in contact with the oxygen of the atmosphere, bringing about an oxidation of the coating of glue, which must be regarded as the basis for the formation of the grain subsequently developed in the image. The film must not, however, be left too long, else it loses its great sensitiveness, and yields bad and dull pictures. It is difficult for the drying to take place in an oven, but in a warm apartment during (say) four-and-twenty hours, for in this case there is plenty of time for the oxidation to take place. But the latter mode of proceeding is not to be recommended, as the plates are thereby easily injured.

About the time of exposure under the positive nothing can be said of the nature of the cliché and the intensity of the light for the time being has obviously much to do with the matter. A vigorous positive with strong shadows necessitates a lengthened exposure, but this must only take place in the shade—in a window, for instance, looking away from the sun. The direct sunlight makes the picture hard, the half tones are lost, and the result is worthless. The printing is a difficult matter, which can only be accomplished by compound casting, but still there are rules which should guide everybody. The printing is done in an ordinary frame; the sensitive film is placed upon the positive in such a way that the former lies upon the collodion side of the latter. After a little while, the print will appear gradually, the deepest shadows, however, not showing any details, and this is a sign that the printing has not yet gone far enough. Of the light different when the same judgment may be formed by opening one half of the frame, by which means the picture can be more easily and correctly inspected. Before the details in the shadows appear, it will not do to stay the printing. I expose my plates according to the character of the positive, and the daylight, three to five hours, covering up the more transparent portions of the cliché after an hour or two with a pigment, made with lampblack and water, thus allowing the action of the light to print through the more opaque portions of the positive. In this way the half tones of the picture are secured in very good condition. The work is not difficult, neither need one be very anxious about it, for after a little practice one may easily prepare even a plate of large dimensions in this manner in a few minutes.

If the exposure has been a satisfactory one, then the development of the picture is easy. The liquid employed by myself consists of fifteen parts water and one part alcohol, the latter having the property of dissolving the film scarcely so quickly as water alone. The plate is laid in a bath of this mixture, and after a few seconds quickly withdrawn and placed upon filter paper. On examining the picture it will be found that by this operation only the deepest shadows and more vigorous outlines are to be grained. It is, however, to be recommended that the complete development of the picture should not take place at once, so that the glue coating does not absorb too much moisture, and the grain resulting be not perfect. The damp image is allowed to dry spontaneously for a little while, and the development and drying is conducted alternately, in a gradual manner, until the details are laid bare. The finished image is then dried in the air for a few hours, and then put into a water bath to remove any chromate of potash which may still remain in it.

To change a relief of this kind with all its delicacy, by means of the electrolytting process, into a metal engraving plate, it is necessary in the first place to take an accurate mould of the same with some suitable substance. Everyone who has had experience of the process knows how difficult such a task is to perform well, and in this case one has to do with such a fragile and delicate relief, of which a most perfect reproduction is necessary. Paul Pretsch designates this operation as the most difficult of all, and by its imperfect performance was his labour often rendered fruitless. He used to employ some oily or resinous body mixed with gutta-percha, which was rendered fluid by heat, and in this condition poured over the relief. Six years ago I experimented for a long time with a similar compound, but never succeeded in securing a good mould, and more recent experiments have proved to me that gutta-percha brings with it more trouble than advantage. I therefore tried to avoid its employment altogether, and used a mixture of the following composition:

1. Spermacetum .... 425 grammes
2. Stearic acid .... 200 "
3. White wax .... 170 "
4. Araphte .... 70 "
5. Graphite .... 70 "

I first of all melt the asphaltum, and then add 1, 2, and 3, when the solution has been rendered sufficiently fluid by stirring and exposing to a temperature of 70° Reaumur, the proportion of graphite is finally put in.

The advantages of this composition are many. (1) Its fluid character on warming slightly, and therefore its facile setting upon a delicate relief. (2) The mixture hardens when once cold very perfectly, and is solid enough to repel subsequently the action of the graphite and brush. (3) The mixture is quite independent of itself from the impression. I have tried the composition for the purpose, in all sizes, and have always obtained brilliant and perfectly good clichés.

After the picture has been completely developed by the water bath, it is dried by means of good bibulous paper. If the grain is too vigorous the image appears too high. The gelatine picture swells by reason of the moisture, and this is the reason of the coarse grain. It is necessary, therefore, to diminish the moisture as much as possible, so as to impart to the relief the necessary beautiful granulation and other qualities for printing purposes. This is done by passing a fine brush in all directions over the image, principally in the deepest shadows, so that the relief is in some sort dried and stretched; at the same time the grain becomes finer and more delicate. In this way the image is made ready for moulding; a framework of metal is placed around it, and from one corner the pouring on of the composition, warmed to melting point, begins. The separation of the mould from the relief is easily brought about by allowing the composition to set and cool to some extent, and then lifting and turning over the glass plate, when it will be found that the mould has begun to leave the image of its own accord. It is only necessary, therefore, to lift the glass plate somewhat in order to complete the separation. The facility and ease with which the moulding is conducted, as also the smooth and perfect character of the mould itself, will certainly give satisfaction to the attentive manipulator.

When the mould does not feel warm any longer it can be rendered fit for electrotyping by brushing on a layer of graphite; the image will then adhere to the copper being passed over its surface. The image becomes more brilliant still after this operation, and the electrotyping is proceeded with in the ordinary manner.

This is as far as my work has at present gone, and I may say that it affords me great pleasure to publish the results of my numerous experiments, which have been to me a labour of love, in which I have not stinted the Vienna Photographic Society. It is my warmest wish that the interest felt in my native city of the important invention of a fellow-townsmen may remain lively and prosperous for some time to come.
THE PRACTICAL PRINTER IN AMERICA.

XVII.

PRINTING INTENSE NEGATIVES.

These negatives generally print “chalky” in the lights, and “inky-black” in the shadows. In a negative that is too intense there is scarcely any detail whatever either in the high-lights or in the shadows. Such a negative then will yield what may be termed bold and vigorous-looking prints, and will in many cases suit the customers, especially some ladies who like to see their faces very white. To a well-educated person nothing is more repulsive, in the way of prints, than black and white pictures, without any of the fine detail either in the lights or shades, which are now so universally admired. The contrast between the lights and shades in such a negative is too great, and consequently it should be toned down or softened.

It is well known among most printers that the slower a negative prints the more contrast there will be in the resulting print, and vice versa. Such a negative, then, should be printed as quickly as possible. A too sensitive paper will make the contrast all the greater, and our object in this case, then, is to have a paper silvered in such a manner as to obtain a print less harsh than would be obtained in the ordinary way of working. Paper, then, should be chosen especially for such negatives, and kept separately from that used for the rest, for when a paper which produces fine prints from intense negatives would produce miserable ones from weak negatives. The paper should be silvered only a very few seconds on a weak bath (say from fifteen to twenty seconds on a 35-grain bath for the Berlin brand of paper, for the Hovey brand fifteen seconds on a 25-grain bath, and for other brands say this is the rule). A paper used for fine prints on a 30-grain bath, and for the opaque prints may be used to good advantage. After toning, if the paper is damp, dry it, and then after cutting it up to a suitable size for printing, place it in a box which is labelled “Paper for Intense Negatives,” and always use this box for this brand of paper, and then there will be no danger of mixing it with the differently sized silvered paper which is used for printing other kinds of negatives.

We always use the pink paper for intense negatives, for the colour of this paper is of great benefit to the print, as after it is mounted there will be a delicate pink or flesh colour to the high-lights, which will look very much like the original in the negative and tend towards giving the appearance of detail in these parts. The paper is most chalky, such as the hands, &c. After having filled a negative-box, containing one of these intense negatives, with a piece of the paper which was prepared for it, we will place it out in the sunlight to print. The more direct the rays of the sun fall on this negative the quicker will it print, because the light will be correspondingly brighter. This is the reason why, when we place a negative out to print in the sunlight, it prints quicker than when placed in the shade, and when placed face up to the direct rays of the sun it will print much quicker than when the rays strike it obliquely, as, for instance, when the printing-frame is laid down flat on the printing-shelf. Consequently I recommend, for very intense negatives, to place the negatives face up to the direct rays of the sun.

One of the easiest ways to tell when the board is face to the sunlight is to drive a tack perpendicularly in the printing-frame, and in placing the board out to print place it so that the tack will not cast any shadow except where the sun shines direct upon it, and then a place as large as the head of the tack alone will be shaded on the board. The way I generally do is to place the board so that the shadow of the board is cast by the same line continuing from the sides of the board—in, i.e., a straight line from the sides of the board will run in exactly the same direction as the shadow cast. An easier way, perhaps, to do this is to place your finger close to the board, so that the shadow will come on your finger at exactly the place where it commences to extend out beyond the sides of the board. Do this on all the sides, being careful that in getting the shadow right on one side that you do not lose it on the opposite one. When you have obtained the correct shadow, you can with certainty say that, for the time being at least, the negative-board is correctly placed face to the rays of the sun. Keep the board in the sunlight, and move it until I commence to see the light flickering along all of the sides, then I know that the board is all right without the use of my finger. You will soon get used to it, and after the first few times it will not be necessary to place your finger there, and it will only take two or three seconds to place it exactly right with one hand, while with the other you can be taking up another board to place out to print. The advantage of the above plan can readily be seen by those who print those styles of prints known as “Mezzotints.”

One disadvantage in placing the intense negatives face to the sun, without either ground-glass or tissue-paper over them, is the liability of there being some bubbles, scratches, &c., in the glass, which would print on the paper, and these would be the cause of great trouble in finishing them out. In this case, then, the use of tissue-paper will often prove of great advantage. Many times have I been annoyed in the same manner in printing such negatives, and then would be obliged to place a ground-glass over the negatives, if the defects were very small, and a couple if they were quite large, to avoid their being printed. Sometimes even a tissue-paper must be used to fully answer the purpose; hence the consequence of using tissue-paper. In printing negatives which are to be cut into plates and furnished with borders, the shadows are a trifle darker than you wish them to be when done, and then take the print off and examine it. “Print for the shadows, and let the lights take care of themselves,” is a very good motto, and worthy of notice in printing intense negatives. On examining the print, if the lights of the face are very white, so as not to contain much detail, then they should be softened.

There are various ways of doing this, and one of the best in many respects is that of making an aperture full as large as the place to be shaded, in a suitable size piece of yellow envelope-paper, and holding the print in the left hand and the envelope-paper in the right, hold them both out in diffused light, and tone down the blanky whites of the print. Care should be exercised in performing this. The removal of too much of the print will nearly spoil it, and then the print will not be in the position for being cut. The paper should always be on motion while out in the sunlight, so that there will not be any sharp line on the print. The place to be softened should be darkened a very little, two or three seconds’ exposure to the sunlight, and half a dozen or so more in the diffused rays, being all that is generally required. Never attempt to shade a print in this manner unless the hole in the paper is full as large as the place to be shaded, for with a smaller hole you will most probably spoil it, by shading it irregularly. The shaded place should also be a trifle darker than what it should be when done. Practice will soon render you perfect in this little printing dodge, as well as in other at first difficult parts of printing. I have seen many prints very much improved by this method, and then again I have seen many others ruined.

A print printed in the manner described above from a very intense negative will have the following advantages:—1. It will be a bold and vigorous-looking print. 2. It will present fine contrasts without harshness, and will contain softness throughout. 3. There will be detail, both in the shadows and in the lights. As a whole the prints will be much improved, will result in much improvement being obtained from the negative, providing it had been printed without regard to its improvement.
ELECTION OF OFFICERS IN THE PHOTOGRAPHIC SOCIETY

As the first step towards the election of officers in the Photographic Society must be taken within the next few days, it may be useful to those of our readers interested in the Society if we briefly state the working of the new laws in relation to election, which come into operation this year for the first time.

Under the new laws the election of the officers will be effected by the ballot of the whole of the members of the Society, whereof two-thirds of the entire vote of those by birth or adoption might attend the annual meeting. The nomination of officers is also left entirely in the hands of members, no house list of new officers being recommended by the existing council as heretofore. Every member of the Society is at liberty to nominate gentlemen to fill all the vacant offices, the sole condition to give legitimacy to such nomination consisting in putting them forth in writing. Of such nominations all such nominations must be in the hands of the Secretary not less than twenty-one days before the annual meeting. From the lists so received the Secretary will prepare ballot papers, which will be forwarded to every member of the Society, each of whom, having duly received his vote, must send in his ballot paper to the Secretary in time for the annual meeting. The ballot papers will contain a complete list of the names, with the names of their nominators, and the member will erase, before returning it to the Secretary, the names of all but those for whom he desires to vote, leaving of course the full number of officers to be elected. To give this voting the real quality of the ballot, which is, of course, secrecy, the marked paper is to be returned to the Secretary without any name; but in order to identify it as coming really from a member of the Society entitled to vote, it must be returned in a special envelope provided by the Society for the purpose, which will be forwarded to each member of the Society together with his voting paper. These envelopes will all be placed, unopened, in the hands of scrutineers to be appointed by the Society, by whose advice the results will be made known at the annual meeting.

So far as we can see, the course is simple enough, and not open to any kind of cavil on the score of narrowness. Every member is eligible for office; every member can nominate; every member can vote; as the vote is secret, no kind of undue influence or cliquism can easily come into operation. Possibly the objection may be raised to the effect that the machinery is somewhat complicated and extensive for the simple purpose of selecting officers to carry on the business of a scientific society with eight meetings in the year, but as it is possible this elaborate machinery may effect the purpose, and in preserving the Society from petty jealousies and divisions, it is probably desirable to adopt it. Another objection which we have heard raised is to the effect that in the absence of a house list, the Society might find that through the forgetfulness or indiffidence of the members generally, no nominations whatever had been made, and hence no officers could be elected. This objection is, however, based upon a misconception or oversight. As all the retiring officers except the vice-president are eligible for re-election, those would always stand as practically nominated, should the members generally fail to re-nominate them or to nominate others. There is, however, little risk, we hope, of such supine indiffidence as an entire absence of nominations would indicate.

The election of this year will differ, not only from all the past, but from future elections. At the present election of officers on the reconstitution of the Society, all the gentlemen accepting office did so with the understanding that the position was temporary, and that at the next annual meeting a general election, under the operation of new laws, of all officers, would take place. At that election, the first in which every member of the Society had an opportunity of taking part, there were no special nominations, every member being on the vote of the whole house. In future, nominations must be made, and such nominations must, as we have said, reach the Secretary twenty-one days before the annual meeting in February; that is, they must reach him, addressed to the rooms of the Society, 9, Conduit Street, Regent Street, before Tuesday, the nineteenth of the present month. The offices for which nominations are required are president, vice-presidents, a subscriptions officer, and eighteen members of council. In future years six new members of council only will be required, as well as a president and one vice-president, two-thirds of the council, and of the vice-presidents remaining in office, while a third-retiree in rotation, to give place to new blood if such an infusion be required.

The new laws, which have passed somewhat in haste at a special meeting at the close of the session, may be legibly revised at the coming annual meeting. Whilst it was manifestly desirable that the revised code, upon which the council had laboured hard, should be submitted to the members before the recess, it was scarcely possible that it should not possess some minor points admitting further revision or improvement. It was enough that a broad principle of fairness was embodied in the new code, and whether it had proved necessary in practice or not, was desirable to meet the wishes of some members. Any modifications still necessary or desirable are possible at the annual meeting; but it will be necessary for any one concerned in securing such modifications to give due notice of motion at the meeting on Tuesday, in relation to any alterations he may intend to propose at the annual meeting in February.

PHOTOGRAPHIC QUALITIES OF VANADIUM SALTS.

We recently remarked that a large unworked field still remained open for the researches of experimentalists, amongst substances known to be in some degree sensitive to the action of light, but which have not yet been brought within the range of practical photography. Another class of salts has recently been added to the series contained in that extensive field, and is indebted to Movers, Johnson and Mathey for details of some exceedingly interesting experiments undertaken by Mr. James Gibbons, for the purpose of testing the photogenic qualities of certain vanadium compounds.

Vanadium is a somewhat scarce metal, found in certain iron ores, and also in combination with lead. It seems to have many characteristics in common with chromium, and as it is not improbable that its photographic qualities would be found on further investigation to be similar. Vanadic acid, like chromic acid, is of an orange-red colour, and most of its salts are red or yellow. Gelatine, when exposed to light in combination with some of the vanadium salts, becomes insoluble when treated with a solution of nitrate of silver. Paper treated with a vanadium salt darkens under the
action of light, and when treated with silver, gives a vigorous image like some uranium salts. A silver compound of vanadium gives an image which may be developed with salts of iron.

The record of Mr. Gibbons's experiments stands as follows:—

"Potassium divanadate, in combination with organic matter, is first rendered green, and ultimately blue, by exposure to varying degrees of light; then, after being exposed to light, it is shown that the solution does not acquire the same property to which it was submitted. The salt does not undergo any change when exposed to diffused daylight. Paper which does not contain any size of an animal origin, when treated with a solution of potassium divanadate, is thickened on exposure to light, the depth of tint depending on the length of exposure and on the strength of the solution used. The tint, however, never becomes darker than a slate colour. If the paper thus prepared is immersed, after exposure to light, in a solution of silver nitrate, the colour in the exposed part instantly changes to a deep brown or to a black colour, varying according to the amount of silver nitrate. A tint of the decomposed vanadate, which is of such an amount as to be with difficulty distinguished from the whiteness of the paper, will, by immersion in the silver nitrate, be toned so as to exhibit a very perceptible tint. It is evident that paper prepared in this way might be employed for the purposes of photographic prints. The exposed parts are converted by treatment in the silver bath, into yellow silver vanadate. This substance may be dissolved out either by ammonia or by sodium hyposulphite. This act of fixing converts the dark brown or black part into those of a red colour. This may be prevented, to some extent, by using a bath of ammonio-silver nitrate, with an excess of ammonia instead of the amount of silver nitrate before mentioned. The developed parts, after being toned with gold chloride. The length of exposure required to produce a deep black is about one hour to a strong sunlight: this, by using a solution of the sodium orthovanadate containing about one per cent. of the salt. Some ligneous substance only must be present with the sodium orthovanadate for the production of the above-mentioned slaty tint; for if an albuminous body be present, a faint brown tint is produced after exposure to light, and the silver nitrate is not afterwards reduced to any very great extent. The slaty colour of the reduced salt appears to be due to the formation of vanadium trioxide. If the exposed paper be kept for some weeks its colour changes to that of a yellowish-brown, free vanadio acid appearing to be produced. The liquid decomposed with sodium orthovanadate, exposed to light, and afterwards dipped into a solution of silver nitrate, becomes insoluble in hot water. Silver orthovanadate is capable of forming a photographic image, which is nearly latent, and which may be developed by the ordinary ferrous developer used in photography. To produce this image, two or three minutes' exposure to sunlight is required. To develop it, it is essential that little or no silver nitrate be present; otherwise, the exposed and unexposed parts are reduced indiscriminately. The washed silver vanadate can be mixed with a solution of gelatine containing a little albumen, spread upon paper and allowed to dry; it can then be exposed to light, and afterwards developed."

* Communicated by Prof. Roe, to the Literary and Philosophical Society.

FRENCH CORRESPONDENCE.

SPOTS IN PHOTOGRAPHIC PRINTS—BAD CARDBOARD—LEIPOLD'S PHOTO-ENGRAVING PROCESS—MARC ANTOINE GAUDIN—GRANTS TO SCIENTIFIC MEN.

The subject of stains or spots upon prints arising sometimes even during the operation of printing, despite the exercise of greatest care, is still occupying the attention of our photographers, who are naturally very anxious to discover the true cause of this fatality, so vexing both to themselves and the public. For this reason, it is well to call again to consideration all the experiments and opinions known on the matter, and I propose to bring before your readers a communication which I have just received from M. Bandoux, of Jersey.

This gentleman attributes this peculiar kind of smallpox in photographs entirely to the composition of the cards upon which the prints are mounted, and particularly to those cards which have been manufactured since the war. The proof of this is to be found in the following circumstances:—

M. Bandoux always draws his supplies of albumenized paper from the best Paris houses, and invariably chooses that of the finest quality. He has not changed for some time past his method of sensitizing, toning, fixing, and washing, his manipulations, to be brief, being thus conducted. The positive is put in the bath at the beginning of the year and maintained at fifteen per cent. strength, the dark room where the operation is conducted being warmed in winter. The toning bath is that recommended by M. Davanne, and the fixing with hyposulphite of soda is the process ordinarily adopted. Finally, the washing is organized in such a way as to completely remove from the prints the hyposulphite that has been absorbed by the prints.

To do this, M. Bandoux employs a round dish with a double bottom, 1:25 metre in diameter and thirty centi-metres deep. The two bottoms are separated by a space of six to eight centimetres, fitted with a big tap, which permits the water to run away at will, with more or less rapidity. The upper partition is pierced with holes like a sieve, and it is upon this that the prints remain. On two sides of the dish are placed two tubs, but at a higher elevation than these. These are always full of water, and to each is fixed a tap in a slanting position, so that the water is poured in in the same direction against the walls of the bath, and turns the prints continually, forcing them towards the middle of the bath, whence they are again dissociated by a third jet of water in the centre coming from a cistern. The water to replenish the tubs and the cistern is provided by pipes coming from a neighbouring rivulet.

The prints are allowed to remain in this bath for at least six hours, and often all night long, and as the water is running out continually through the tap between the two partitions, no trace of hyposulphite can possibly remain after such a thorough rinsing.

For mounting, M. Bandoux prefers to use a paste made with distilled water and French starch made in Paris. English starch generally contains a blue pigment, and appears to be of an inferior character. The starch is made fresh every day, so that there may be no fermentation.

M. Bandoux draws his supply of cards from the best house in Paris, and he has pictures mounted eight years ago upon which no spots or defects of any kind have or defects of any kind have manifested themselves. Not one of those which have been mounted in albums upon coarse paper have undergone the slightest alteration. During the war at Paris, not being able to procure any further supply of card from Paris, he purchased, at Jersey, some common card such as is to be found in all shops. Photographs mounted upon this material have kept very well, but some of the cards bore spots. The spots were then told in Paris at a correspondent in Paris a supply of 20,000 cards, for which he was kept waiting some time, by reason of the number
of orders in hand. After a time, however, the supply was made, and the cardboard was used in the ordinary way. Six months elapsed, and then complaints began to be made on all sides about defective prints, which were full of spots and stains. At first it was believed that the assistant who had charge of the fixing was at fault, but soon it was apparent that the failures took place so regularly that this reason could not be the true one. Then the hypoosulphite of soda was suspected, and a supply of the purest material was sent for from London. Despite all these precautions, however, the prints continued to appear with the vexatious spots upon them, and even a change in the albumenized paper made no better. In short, the portraits mounted on the 20,000 prints were all of them more or less injured after a little while.

Certain facts were tolerably certain. The portraits mounted upon the cards coming from Paris before the war did not show signs of any defect. Those mounted upon thick paper in the albums were likewise free from any of the spots. Those photographs mounted on the cardboard purchased in Jersey were in a bad state; and other pictures mounted on larger boards kept in a good state of preservation. Finally, what was very conclusive was the fact that the drawers filled with unmounted prints did not any of them contain spoiled prints, although many of the pictures had been produced eight years ago.

Mr. Belloc asks whether some preventive measures could not be taken to preserve the print from the cardboard, by coating the latter with some sort of preservative, and he thinks that india-rubber might be a suitable material for the purpose.

My correspondent adds that for some time past he has used the "cole ramie," which may be employed by a thick coating of it in the proportion of one hundred grammes of cement to eight grammes of glue, and that when the mounted prints dried by heat do not become detached.

M. Joseph Leipold, Director of the Photo-engraving Establishment at the National Printing Establishment at Lisbon, has sent me a collection of specimens by the process, of which the PHOTOGRAPHIC NEWS published a description in its last number. These specimens, which are of the most varied character, containing both reproductions of paintings and views, reproductions of monuments, and works of art, are most remarkable in many ways. They possess great detail, much delicacy, an extraordinary relief, and considerable vigour. They may compare favourably with the fine plates produced some time ago by M. Charles Negre, and at the present day by M. Rousselon. We cannot but congratulate M. Leipold on the success of his undertaking, and thank him, moreover, for publishing to the world the method by means of which they have been obtained.

In the letter which accompanies the interesting collection M. Leipold very modestly attributes the best part of his success to the valuable assistance he derived from our mutual friend M. Carlos Relvas, the skilful amateur photographer of Hollegus, whose works are well known in England and France by all those who visit photographic exhibitions.

It is, in fact, with the assistance of M. Relvas's very perfect cliché that M. Leipold has been able to prepare all the plates that are produced in the National Printing Office of Lisbon, and everyone knows that in mechanical processes of this kind the nature of the cliché is a matter of great importance. It is gratifying that the co-operation of these two gentlemen has been productive of such valuable results.

I am sure all the readers of the PHOTOGRAPHIC NEWS will learn with pleasure that a presentation has just been made to our old friend Marc Antoine Gaudin, whose works, especially in the early days of photography, contributed so much advancement. M. le Baron Trémont bequeathed to the Academy of Sciences a further sum of eleven hundred francs to aid any savant who needed assistance in work that might accrue to the use and glory of the French nation; this sum has just been awarded to the persevering experimenter to whom we have alluded.

In regard to this matter, I may mention that I have before me the Comptes Rendus of the Academy of Sciences for the month of December containing the various grants of money distributed on that occasion. It is a quarto volume of not less than 200 pages, and the works which are therein mentioned belong to every branch of science. There are few reports in which the art of photography does not figure. In all kinds of researches the new art has become an auxiliary, and in some alabim indispensable. Physiology, anatomy, botany, zoology, geology, mineralogy, microscopy, natural history, medicine, use of the camera, and every day the application becomes more widespread—the process is so prompt, so exact, and so infallible. In reading the reports one is more and more convinced of the important rôle that photography plays in scientific discoveries, and in this respect, at least, it must be conceded that photography fulfills a most valuable function.

Ernest Lacan

THE TRANSIT OF VENUS.
The Eve of the Transit.

An interesting letter from the Special Correspondent of the Daily News and Telegraph to the Editor of the American Journal gives some very interesting details of the preparations on the day before the Transit. He says, dating Dec. 8th:

To-day a general polish, oiling, and dusting has been given to the instruments. Everyone has been surrounded with small screws, bolts, sperm oil, cog-wheels, brushes, and dusters, from the small hours of the morning. Such a furusting up I much doubt if half the instruments have ever had before. Then, too, the observers have been committing miraculous seats which should give them the greatest ease at the critical time. Chairs have been placed, seats to make platforms, barrels, spars, planks, and so on, have been "requisitioned," and the whole encampment has the general aspect of being supplied with very Irish furniture. There has been a council respecting the signals to be given to the photographers as to when they should expose their plates for recording contact, and finally it has been arranged that Colonel Campbell and Dr. Avraes should both give signals, and that Captain Abbey should be left to decide at the time as to which he should note. The signals themselves are not novel. The colonial, as his profession demands, has chosen the ready means of firing a broach-load, whilst the learned doctor has been more particular in his mode of expression, standing in a row of five, signifying to those in the third to go when the sun is at a certain degree of elevation, by absence of sunlight, or the loss of the stars for an evening. Thus, I see out of my boat that they all, one by one, are constantly making preparations that are too useful for words.

If constant watching has any effect on the clerk of the weather, he certainly will be bound to give them a favourable time of it in the morning.

Since I last wrote we have all been hard at work practising on the model transit, both by night and day. The lady astronomer has been most zealous, and her observations, I fancy, will certainly not be wanting to any. The personal differences in observations, even each observer has been duly noted, as it has been found that some observer see the phase of apparent contact of the limb of Venus with that of the sun somewhat earlier than others. The time of true contact will be deduced as follows:—Dr. Avraes, the exact optical contact of which has been seen and is daily determined by a small microscope placed in proper position. The sun and planet of course are represented by the model, the former being represented by a circular opening behind which is flashed either sunlight or also lamplight, whilst the latter is simply a black disc moving in front of it, by either clockwork or a slow-motion screw. Each observer takes a turn at the model, his telescope being some 200 yards distant from it, and by signal stops the movement when he fancies contact has taken place. A scale attached is then read, and the number of seconds noted by which he is distant from the estimation. It standing by the daily daytime and adjusting the mirror. A sun which makes a blackened bulb thermometer rise to 160 degrees is apt to feel too warm; and when one has to face the "crowd" the average has been to allow for a couple of degrees less in the thermometer, and this being such a minor degree, becomes rather checked. To-day we have made our arrangements for placing a cordon of sentries all round our camp. No one will be admitted or allowed inside. Even our farmyard companions have been cooped up till further orders, last
their quacking or quacking should disturb us while listening to the tick of our chronometers. We rather expected a Cook’s tourist party to have been here by now; probably it had been generally known in the evening that there would be an eclipse of Venus in the attraction of seeing philosophers at work might have proved an inducement for getting to Thves thus early, and have been trying to us. The only Europeans besides ourselves here now, however, are the Trews; hence was not the inside of the Diet Vero will not be invaded by any Ferrangia pilgrims, and that we shall be left undisturbed. The programmes for to-morrow is, a five o’clock break; and the evening’s optical comparison of chronometers with the adjustment of instruments, and arrangement of details. At a quarter to seven the sun will appear, and he will be watched and photographed till a quarter to nine, when the transit of Venus will be finished.

Dating on the 9th ultimo, after briefly referring to the successful results, he proceeds to details of the actual operation. He says:

This morning, long before daybreak, we all bundled out of our boats, took chronometer comparisons, and a juxted instruments. It was rather cold, and pop-jackets and mufflers were quite necessary to keep oneself warm. As it got near sunrise every telescope was pointed towards the spot where the sun was expected, and at last he made his appearance in a delightfully bright sky. Almost immediately A. H. Campbell shouted out, "Here it is," and then there was a general31

January 8, 1875.

ON FINISHING AND IMPROVING LARGE NEGATIVES.

By George Crompton.

I presume that as Mr. S. Fry has tried and made known his success with the so-called Lambert-type process, others will be induced to try it, and as a few practical directions are always of use in preventing blunders, I purpose in this paper giving my experience for over twelve months, and practical hints as to working.

The Lambert-type process, because I cannot give up my claim to having published, nearly twelve months before the date of the patent, a method of finishing enlarged negatives by working upon tracing paper upon both sides of the negative. It matters nothing that the main object of my paper was to give practical working directions of a process of making enlarged negatives, which I considered, and still consider, the easiest, and simplest in working; what I say is (and anyone can see if my claim is just by turning to the back numbers of the News, in which my paper was published) that at the conclusion of the paper was a paragraph devoted to various methods I had adopted for retouching or improving the resulting negative, and among them I mentioned that I had found the use of tracing paper on both sides of the negative to be very easy and artistic method of obtaining effects which I could get by no other means, and exhibited a large-size negative which had been done by that method; and there are more than one member of the South London Photographic Society who can prove that some time before the reading of my paper they saw in my studio, in Shepherd’s Bush, enlarged negatives, which had been traced upon with pencil and other materials—notably one of the late Emperor Napoleon III., done for the Stereoscopic Company. However, it call Lambert-type or any other name, it is free to all, and it places in the hands of a photographer of taste a wonderfully efficient method of altering and improving large negatives of all kinds, for life-sized direct negatives can be improved, and made more artistic (where they require it) in its use, just as well as enlarged ones; but it is, of course, of most value for improving enlargements.

First, as to materials required. The first and most important is the tracing paper, and here I differ from Monsieur Lambert in preferring a sample that is not transparent, for reasons which will appear in the details of working. It can be obtained at any artists’ colourman; I get mine from Howey’s, Rathbone Place. The most important point is to get it of a very soft and smooth quality, (as the rough paper is not fit for this use), just as clean, and free from opaque spots; and you must be careful not to fold it, or it will crack, and the crack will become more opaque than the other parts, and so cause a light streak on the print. I use pencils of four kinds (H, HB, B, and BB), also powdered lead or plumbago (the best I have used was supplied by Mr. J. Werge, with his process of making pictorial background), cotton-wool, and plenty of clean soft carded cotton, or cotton wool.

Having obtained your negative and varnished it in the usual way (and I neglect no dodge or expedient to make the negative as perfect as possible, for in my experience I find this method of retouching, as every other, will succeed best upon good work, and this or any other dodge, will make a print half done for you), you then take off the tracing paper is cut to the size, and dampened by pressing evenly over it a sponge which has been dipped into water, and then squeezed nearly dry in the hand. A brush with the ordinary office gum is run round the edge of the negative for about a quarter of an inch on both back and front (care having been taken to clean the back of the negative of all stains and dirt), and the paper is then brought into contact with each surface. Be careful that the gum does not spread too much. When dry, the paper will be strained quite tight, and present a very agreeable surface for working upon.

We will suppose that the negative to be manipulated is a twenty by sixteen enlargement of a lady in black silk dress; the background is decorative in the small negative, and in the enlargement it is very uninteresting. The negative has been well exposed, and developed with a strong developer. It is placed upon the retouching desk with the, negative side to be worked upon first; with the H pencil go carefully over the face, working out spots, freckles, and other inequalities, but doing no more than is absolutely necessary to mend the negative. Taking now the HB, with both, decided touches, set out on all high lights wants want to be done. The pencil is then placed upon the white ruff round the neck, the nose down the front of the dress, all jewellery, the light upon the eyes, &c. Now turning the negative over, I take the B pencil, and put on the high lights upon the face boldly and strongly; the two lights upon the forehead, on the brow, and over the eyes are rubbed in without care for the edges, but with, great care that they
are in the right place, down the nose, and upon the chin, and if necessary upon the cheek bone (in these sometimes the B pencil is not dark enough, and the BB will have to be used). Having satisfied myself that the masses of lead are in their right places, and that they are much more opaque than they are required, I take a small top of cotton wool, roll it into the cuttle-fish powder, and lightly rub over the lead, rubbing harder upon the edges, graduating them into the paper with more powder. We will suppose that the shaded side of the face, and the shadows under the eyes and chin, are too heavy; with the same piece of wool I mix some of the cuttle-fish powder and plumbago together upon a piece of dampened and well white paper, over those parts. You may ask why this is not done with the pencil; but you will find, as I have by experience, that the cuttle-fish powder being mixed with the plumbago makes it take to the paper in a fine even layer, without texture. Any part of the drapery that may want shading may be done in the same way. Now, to get rid of the background, in a cardboard tray, mix the plumbago and cuttle-fish powder, mixing them well together; rubbing my forefinger into this, I rub it on the tracing paper on the back of the negative, carefully rubbing into the lines of the figure; if this is in some parts too intricate for the finger, I supplement it with the BB pencil. Sometimes the outline requires that the front surface should be worked upon with the pencil, but I find this subjects it to a large extent to the plumbago or cuttle-fish. Upon the rubbing the plumbago over the edges of the figure on the reverse side to the hard cutting outline, which is the result of working upon the surface which comes into contact with the sensitized paper. You will have noticed that all this work has been upon the lights of the negative. Now comes the manipulation of the shadows. With the prepared gum solid by a gum diamond on the reverse side of the paper, the revolving turntable with deep shades which will make the tracing paper more transparent in those parts, and so cause the light to pass through and give greater depth in the print; this gumming must be done with a large brush, and with particular care, sharp decided shadows can be made (which are just like decided touches upon the print with a full brush of colour) by gumming the very deepest shade upon the proposed mix; but you must have some knowledge of drawing to do this with effect. The negative is now ready for printing, which is done in the usual way, with the exception that I take the precaution to cut a rough brown paper mask to protect the background. When printed, the print is of course upon white background.

I must leave the printing-in of the background, and the experiments adopted for getting effects of light and shade into, and upon, another paper.

ALBUMEN FERSUS GELATINE, AND FIXING WITH SULPHOCYANIDE OF AMMONIUM.

By G. BUXTON.

It is generally thought that the undissolved albumenate of silver is one cause of a print upon albumenised paper turning yellow. I am not about to deny this, but to relate the following experiment.

I printed, fixed, and washed a print upon ordinary albumenised paper, sensitised in the ordinary manner, one upon my own sensitised albumenised paper, and one upon paper coated with insoluble gelatine. I then suspended the three prints in a current of warm air. I then removed one print, and cooled the atmosphere, and kept it beneath a lamp for the bottom water half an inch in depth; the prints did not touch the water by two or three inches. The jar was then placed in a strong light that tell upon the three prints equally. After several months I removed them from the jar, and all three have become slightly yellow from the long-continued action of the damp air. I expected the gelatine print would have kept whiter than the others, but it was quite as yellow as the one on ordinary albumenised paper, whilst the print on my own paper was whiter than either. This experiment seems to suggest that albumenate of silver may have received more blame than justly belongs to it.

It is also said that as albumenate of silver is not dissolved from the prints by sulphocyanide of ammonium, that salt is not a fixing agent. The following is the result of an experiment I made two years since. I fixed two ordinary albumenised prints, one with hypo soda, and the other with sulphocyanide of ammonium, and well rinsed them for about half an hour. I then hung them both in a strong light, an exposed to the air in a large glass room for nearly a year, and whilst the one fixed with hypo soda had become slightly yellow, that fixed with sulphocyanide of ammonium remained perfectly white, which seems to suggest either that albumenate of silver has been much calomelated, or that sulphocyanide of ammonium dissolves it out of the print.

ENAMELLING CARTES.

BY A RIVERSDALE LADY.

Clear plate glass with dry whitening, or whitening with an emulsion; varnish the plate with spirit varnish (I find the French Sochees varnish the best). The plate should now be perfectly transparent, without any streaks. Immerse the print in warm gelatine, about the strength of

| Gelatine | 1 ounce |
| Water | 8 ounces |

Put the print in contact with the varnished plate. Squeeze out the air-bells and superfusious gelatine with a glass rod. Lay aside in a dry place for about 10 minutes, then rinse back of the print with warm gelatine paste. Put the dry mount in contact with the print, and quickly put all in a strong printing-frame, and put as much pressure as the plate glass will bear. Lot it remain in the frame for two hours; then take it out and leave in a dry place. When dry, the carte will leave the glass of their own accord; no heat must be used.

Another Mode.—After the plate has been varnished as above, cover the varnish with a coat of warm gelatine. Immerse the mounted cartes in cold water for a few minutes; roll them in a coarse towel, and, while damp and pliable, put in contact with the gelatinised plate. I sometimes wet the plate with water to draw out air-bells, but I think the most brilliant results are got when no water is used. If the cartes are intended for use, and it is wished to press the print can be mounted on strong drawing-paper, and remounted after being raised. I have tried all the different modes of enamelling that I have seen in the journals, but found them very troublesome and uncertain. And on seeing how easily a varnished negative left the glass when put in warm water led me to try how a varnished plate would do for enamelling. And I think if some of our star photographers would give it a fair trial, they would find it more certain, less troublesome, and the result more brilliant.

PHOTOGRAPHY AND THE MAGIC LANTERN.

By J. H. BIXIG.

Photography affords a ready means of producing slides for dissolving views or for use in the single lantern, possessing an amount of detail and a truthfulness which cannot be approached by the most skilful artist, the only drawback to them being the want of colour. By a combination of handwork and photography, however, many excellent coloured designs may be executed, possessing very great delicacy and finish.

I have tried every process for the production of lantern slides which I have heard of, including painting in varnish colours and in water colours, transferring by diaphan and vitremanie and photography, both alone and with hand-drawing. Of these, water colours may be discarded altogether as being devoid of brilliancy, and diaphanie as superseded by the more facile and satisfactory process of
vitremanie. Some excellent designs are sold for this last by a London firm, but the price—five shillings for a sheet of twelve subjects—is rather high, and the instructions issued for the manipulations are anything but clearly and fully explained. In one paper supplied with the designs directions are given for wetting the glass before applying the subfeeder, while in another description of the process no mention is made of wetting the glass. Some of the mechanical slides, too, appear to be printed the wrong way—for instance, in the "Court of Beasts," where the animals are intended to pass before the lion, the latter is printed with the face turned one way and the beasts the opposite; but as the fixed glass having the lion on it and the other glass having the beasts must be placed face in the lantern, whereby the relative directions are reversed, the beasts when moving forward will come, as it were, from behind the lion, whereas they should advance facing him.

In producing slides by hand in varnish colours the chief difficulty appears to be drawing on the small disc of glass outlines which will bear magnifying to the required degree, without becoming glaringly coarse and abrasive; photography, however, affords a ready means of getting over the difficulty, and I have found the following methods of applying it produce excellent results. A design of any subject required is drawn accurately and neatly on a smooth white piece of paper, in pencil or India ink, within a circle of nine inches or more in diameter, and all the details of the subject which are to be represented by black, whether in full depth or any gradation, are drawn in; this is then copied as a reduced negative of the size suited to the lantern employed, in the camera and transparencies obtained by the wet or dry plate process or by using carbon tissue. The designs are then varnished with negative varnish, and coloured brilliantly with proper wash colours.

It will be obvious that the execution of the drawings on paper, and on so large a scale, is a very easy matter compared with working on a slippery glass surface and of only one-third the size. Having made a chromo-plate frame, in which the glasses are movable, and one pair may be readily substituted for another, I have used the method described for producing the various patterns.

The transparencies are printed by the carbon process generally, on pieces of thin glass three and a half inches square cut out exactly to the size required, fitting accurately in the revolving brass work. This requires some care, as it is not only necessary that the disc should be neither too large nor too small in diameter, but the centre of the design and the centre of the disc should actually coincide.

Another way, which I have found very convenient for producing the chromo-plate glasses, is to draw the original design on paper in India ink on a large scale, and as a negative, all parts to be coloured or transparent being perfectly black. It is only necessary then to take copies in the camera of a size suited to the lantern in which they are to be used, and to cut and colour them as before described.

As an illustration of the application of the method I have endeavoured to describe, I will give the details of a dissolving effect produced by it, which I think is somewhat novel. A swan is drawn in outline with India ink on paper, within a circle of nine inches diameter, and shaded to represent the ordinary bird familiar in the northern hemisphere, together with the water on which it swins and the surrounding scenery, the paper being left white in all parts which are to be coloured or transparent. From this two positive transparencies of the exact size required for the lantern are obtained. In No. 1 the sky, water, and scenery, as well as the beak and legs (where visible) of the bird, are appropriately coloured, and the plumage and reflection in the water painted black. In No. 2 the sky and scenery are stopped out with black, also the water, except the reflection of the bird. No. 1 is shown on the screen first, the swan then appearing as a native of Australia, where black swans abound and a white one would indeed be a rare avis. The light from the second lantern, in which No. 2 is placed, is gradually uncovered, and the swan slowly changes his plumage from black to white, the scenery, sky, &c., undergoing no change.

Correspondence.

REMOVING STOP DURING EXPOSURE.

Dear Sir,—I see by Mr. Wile's letter in this week's News that he has found the great advantage of removing the diaphragm during exposure. The operation is rendered more simple and certain by drilling a hole through the projection on the stop, and tying a piece of thread therein, the use of which is obvious. I have succeeded in moving the rotating stops of a landscape lens during the exposure of dry plates, and the resulting negatives were perfectly sharp, the exposure being lessened from ten minutes to four.

Bodelin, Jan. 4th, 1875.

J. B. BRAMS.

FS.—Here is an idea for the improvement of "collodio-chloride" which may prove the most useful process. The presence of those very delicate nitrates in the emulsion has always been a stumbling-block, and they can be removed in the same way that they are removed from Mr. Bolton's emulsion.

J. B.

[The presence of delicate nitrates is at times undoubtedly troublesome when the collodion-chloride is employed for printing on opal glass, and possibly might be got rid of in the way suggested.—Ed.]

TESTING NEW PROCESSES.

Dear Sir,—May I ask space for a few words in reference to Mr. Young's proposal in your last number, and your editorial remarks on the same subject?

The proposal that every new process should be thoroughly tested and reported upon by competent judges is one which must meet with the approval, not only of advanced photographers, who are, notwithstanding their "strange conservatism," willing and anxious to adopt any real improvement, but also of every honest inventor or discoverer of a new process. I hope Mr. Young is himself successful, and which he believes would be valuable to others.

I do not quite agree with Mr. Young that it would be necessary for fifty different photographers to try (and report upon) a proposed improvement, in order that it may be adopted with confidence by others. Surely the verdict of five "good men and true" should be enough to enable others to discriminate between the true and the false.

If a committee officially connected with the Photographic Society could be formed to test and report upon any new process or alleged improvement, it would, I think, go far to do away with "that strange conservatism which looks askance at everything new," and would be the means of introducing many real improvements, while we should cease to hear the bitter complaints of those who have been victimised by the unprincipled "process-mongers." At the same time, the certainty of being fairly dealt with by an honourable body of men would be a great encouragement to those who have time and means at command to devote both to the task of solving some of the difficult problems met with in the daily practice of photography.

But we must not always expect to reap the advantage of every improvement, but give it up in return. Depend upon it, the time has gone by for obtaining, without fee or reward, valuable technical instruction and information, which are the result of patient study and costly experiment.

Let the sale of a new process or improvement which has stood the test be recognised as a legitimate and honourable bargain, and the "man with the secret process"
THE PHOTOGRAPHIC NEWS. | JANUARY 8, 1875.

will no longer be regarded as an enemy against whom we must declare war.

Nor do I see any necessity that the inventor or discoverer of a secret process be regarded as an enemy by the photographically press. Should the time arrive when he desires or improvements cease to be made, no record of progress would be required. I would suggest that if an inventor cannot afford, or does not feel disposed, to give away his discovery, that he should name a certain time during which he desires his process should remain a trade secret, after which let it be freely published and discussed in the journals of photography.

Apologising for occupying so much of your space,—I am, dear sir, yours very truly,

B. J. Edwards.

Talk in the Studio.

THE PHOTOGRAPHIC SOCIETY.—At the meeting of the Society to be held on Tuesday evening next, a paper on a very important and interesting subject will be read by Mr. G. Hooper. The paper will be devoted to a review of the origin, aim, and achievements of the Photographic Society, with suggestions for its further expansion. Mr. Spiller will exhibit a new light, possessing considerate fullness of value, which promises to be a great use in photography. We regret to learn that Mr. Woodbury's illness will again delay his paper on experiments with coloured media.

THE LONDON PHOTOGRAPHIC SOCIETY.—The first meeting of this Society for the new session, just commencing, will take place at the Rooms of the Society of Arts, Adelphi, on Thursday, January 14th, when, after the routine business, a "popular evening" to (which ladies and friends will be admitted) will be given, consisting of an exhibition, by members and others, of lantern slides, by the amateur light, on a large scale. Tickets (free) can be obtained from any of the members, or from the Hon. Sec., Mr. Edwin Cocking, 57, Queen's Road, Peckham.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.—A distribution of prizes, something in the manner of an Art Union, is shortly to take place in connection with the Photographic Benevolent Society. We understand that upwards of 600 prizes will be distributed, chiefly consisting of choices photographs. An announcement in our business columns gives details of the entertainment which will be provided at the annual meeting.

SECRET PROCESSES.—Mr. B. J. Edwards has invited a committee of photographers to test and report upon his secret method of treating the nitrate bath so as to maintain a permanent white, and the committee, while nominating the method, prove satisfactorily the absolute confidence which he himself possesses in the excellence of his method, and in the fact that his secret is worth its price.

A "DREAMY PICTURE."—A recent lecturer remarked that "some of these people didn't know their own imperfections, as the fat old lady who said to the photographer,—I want to be brought out light, airy, and otherlike!"—and who was assured by the photographer that she would make a most 'dreamy picture.'

To Correspondents.

J. Nelson.—It is somewhat difficult to give you full information in relation to the building of a studio, within the necessary limits of an answer in this volume. Assuming that you have full command of position, we should recommend something like the following:—Building a studio with the east and west, so that the principal light shall come from the north; let it be 20 feet long, 12 feet wide, 6 feet high at the eaves, and 12 feet high at the ridge. Opaque at each end. On the north side and roof let 6 feet be opaque at each end, the rest glass to within 2 feet of the floor; south roof opaque; south side may have 8 or 10 feet of glass coming, as on the other side, to within 2 feet of the floor, but the ground, but the background at the west end will probably most commonly be useful. The Belgium sheet glass will answer well,—say. 21-ounces glass. It is cheap, but we cannot tell you the precise price.

B. B. Patterson.—We cannot with any certainty tell you of whom you may obtain views of Liamar and Weston. Formerly Messrs. Marsh and Co. of Southwark would supply you. We believe that Messrs. Catherall and Pritchard, of Chester, have published many Welsh views.

D. London.—There are not sets in London, but we do not know much of them personally. So far as we believe, there is a Catholic chapel in Warwick Street, Regent Street, but we do not know the name of the officiating priest. It is probable that you will obtain views from the Catholic Directory, which any bookseller will obtain for you.

K. (Madras).—The yellow discolouration of your prints is due to the use of dyes for washing the unixed prints which have been accompanies with hypo. These dyes have probably been used before for washing prints after fixation, and slight traces of hypo clinging to them, sufficient to cause this yellow discolouration of unixed prints brought into contact with them. The same cause would prevent any appearance of milkiness when the prints were placed in the dishes. Dish used for holding hypo, and for washing prints whilst any trace of hypo is present, should never be used for any other purpose.

T. S. M. O.—Registration is of no service whatever in relation to any picture in which you do not legally possess the picture, and you do not possess any copyright in portraits taken in the ordinary way of business. You cannot prevent a customer getting his portrait, which you may have taken to his order, copied at any place he may choose. To secure a copyright in a portrait you either have to register it at your own expense at the order of a customer, or you must have secured an agreement in writing with your customer, reserving the copyright to you, and such agreement must be registered at Stationers' Hall.

J. (C.)—We cannot say that the statement has any little obscure; but it seems probable that the iodide solution should be washed off after flowing.

R. B.—It is a matter in which we fear that we cannot give efficient advice. If a tradesman be dishonest or negligent, and after receiving cash neglect to forward goods, he is being brought himself within the operation of the law, we should think; but what form of legal procedure is necessary we cannot say. It possibly may be a civil action to recover the money, or it may be a criminal action for obtaining money under false pretences. A tradesman can decide that after considering all the details of the case. Possibly further pressure and some patience may meet the case.

G. E. D.—The case of fading in carbon prints to which you refer were not examples of fading at all. It simply happened that amongst the earliest examples of Swan's process were some in which the image was attached to the paper by some imperfect cementing material, and portions of the image exfoliated. It is possible, however, tae pigment print may fade if fugitive colours are employed in preparing the paper; but if carbon actually—or, indeed, any permanent pigment—be employed, this risk of fading is less.

R. L.—Glaue has been found best for mounting enameled prints, and the colder it is used the less likely is it to interfere with the glossy quality of the enamel. If the prints are perfectly fixed, the colour will not fade, and if the word is painted after enameiling, as it must preserve them, to some extent, from atmospheric influences.

We cannot without propriety recommend one manufacturer of commercial dry plates as superior to others. We have given reports at various times of the results we have witnessed, but we cannot undertake to give any comparative estimate of the relative qualities of the plates of different manufacturers.

P. J.—So far as experience has gone, it is much in favour of the plan of removing the stop during exposure. The exposure with this stop is of course very much reduced. For instance, if you are using a lens of two and a-half inches diameter, and with a stop of half-inch aperture, a 50-second exposure is required; with full aperture, 2 seconds would be sufficient. If, then, you give the same plate 21 seconds, and I second full aperture, it should be just as fully exposed, with the incidental advantage of a somewhat softened definition, the result of some spherical aberration. It is doubly possible to devise some mechanical contrivance by which the stop may be removed without the risk of vibration. A correspondent, suggests pulling it out with a piece of string. If the lens is mounted in a slanting one, or if you are inclined to one side instead of being quite vertical, it would be more easily removed.

A Painter.—We do not know of any means which will make a person losing both to which the carbonate of soda has been added keep well. An alkaline solution of chloride of gold very soon precipitates, especially when kept in the light.

T. W. W. —Received; many thanks. The matter shall have our early attention.

Received: "Photographic Mosaiacs," 1875; and "Wilson's Lantern Journeys." Several Correspondents in our next.
The Photographic News, January 15, 1875.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

The Return of the Transit of Venus Observers.

Now that we have heard of the success, or otherwise, of most of our Transit of Venus expeditions, and are in daily expectations of hearing the results of the calculations based upon the observations made—whether, that is, we are still about ninety millions of miles from the sun, or whether the distance has been greatly exaggerated, or, else, but barely, very much under-estimated—we repeat, now that the observers have done their work, and handed it over to the calculators to be completed, it is time, we think, to consider how the services rendered by the enterprising scientific men who went out on our behalf are to be acknowledged. There is scarcely any one of those who have gone abroad who has devoted less than three months of his time to the work, being about two hundred days. Probably those who went into Egypt were best off, but these have been away from their home during the most unpleasant season for several months, and have suffered many privations in the cause of science which were far from insignificant. But others were worse off still. Even Lord Lindsay's lot, who went out in his own country, in comparatively comfortable circumstances, is scarcely one to be envied, for sailing about in a tiny vessel among the Indian seas would hardly suit everyone's taste. Then there are those who went to New Zealand; and, less enviable still, the exploring party established on Kerguelen's Land—the Island of Desolation, as it is aptly called—uninhabitable, in the natural world of ships and homes, by the home, by the rocky and dreary icebergs to meet the eye, and with a coast so stormy and inhospitable, that it is a matter of the greatest difficulty to effect a landing at all. Father Perry, one of the professors at Stonyhurst College, and well known as a careful astronomer and skilled mathematician, is in command of the little party of explorers that have cast their lot on this barren island, which is somewhat indefinitely described by sailors as being about two hundred miles to the south and west of the Cape of Good Hope. Being at such a southern point, observations from this station will be of singular importance, and it is to be hoped that the foggy and moist weather, which prevails here for most of the year, will not have prevented the taking of photographic and other records. Of course we shall get them from the ones in the studio, and the longer, about month or two before we obtain any, for a ship must be sent out specially from Cape Town to fetch the little party home, and the stormy and treacherous nature of the ocean near the Antarctic is proverbial. We can never adequately recompense men who thus volunteer on so hazardous a duty; but let us hope that Government and the Royal Society will come forward to do their best, and acknowledge as well as they can the important services rendered. We know it is the rule of the Royal Society to elect but fifteen new fellows every year, and if this number cannot be increased for once, we hope that this year, at any rate, we may see among the new fellows a large number of those who aided most in the recent observations of the Transit of Venus, and thus contributed towards the solution of one of the most important astronomical problems of modern times.

NOTE ON THE CAUSE OF METALLIC SPOTS IN ALUMINIZED PAPER.

BY M. A. DAVANNE.*

Many explanations have already been given of the cause of spots which appear on positive prints, more especially in delicate half-tones and in vignette pictures. To-day I have to call attention to a cause which I have been enabled to follow out for some months, and which is in accordance with the explanations given by Girard and myself some time ago, namely, that the spots are due to metallic particles.

Having to produce a large number of positive prints, I provided myself with a reel of paper which furnished me every day specimens of all kinds and classes of spots, so that ample opportunity was permitted of a thorough observation, which, I believe, has gone no further than myself. These spots I found sometimes isolated, although very numerous in the delicate half-tones and in the skies of my prints—sometimes grouped by chance, like a constellation; sometimes, too, they occupied the same relative position, in one or several straight lines. It was this regular state of things that especially attracted my attention, as it could not have happened by chance; for if the spots are metallic, as I have shown in groups might be attributed to metallic particles themselves spread in the bath, such could not be the case with a series of spots affecting the regular form of a straight line, or curve; and it was necessary, therefore, to look about for some extraneous cause.

In the prints most covered with white spots the albuminized surface of the paper does not present any change whatever. Rarely indeed is this the case. Usually they are in part or wholly black, whence the stain proceeds, from the white halo which produces what we term iron spots; but if you examine the paper by transmitted light with the aid of a magnifier, you will find, as a general rule, the centre of a darker colour, and, turning the print round, you will see a black speck at the back of the sheet. This black metallic spot, or an almost invisible one, is removed by the addition of reduced silver by another metallic particle much finer still, which is attached to the back of the sheet before it is sensitized. The foreign metal reacts upon the salts of silver, either at the period of sensitizing or later on, according to the mode of preparation, and the reaction is shown by a white halo. The quantity of matter is so minute that it is generally visible only in the palest half-tones. How these metallic particles become encrusted on the back of the paper? is now the question to be solved. We can only reply to it by an hypothesis, which, however, is such a logical one, that it will readily obtain belief.

We observe, in the first instance, that these spots generally exist before the prints are mounted upon card-board, which at once relieves the latter from all blame in the matter. They cannot result from manipulations in the studio, for the sheets are left in the workshop for a month and then sent by ship, and all the sheets do not appear injured in the same fashion; and I have tried the papers of two different manufacturers under the same conditions, one of them always giving me spots, and the other none at all; the reason of their appearance has, therefore, nothing to do with the photographer. If we go further back, and pass to the workshop of the albuminizer, we find it impossible to accuse this worthy man either, for the side of the paper that is albuminized is rarely marked with a metallic point; this is always on the back. Moreover, the two papers which we have experimented with were albuminized at the same place, and one only of them proved to be of a spotty character; the other, coming from another manufacturer, was quite free from these imperfections. We cannot, therefore, pronounce otherwise than that the cause of the spots is to be found in the manufacture of the paper itself.

If we push our examination further, we find that these same papers, full of spots on the back, present but very rarely these faults on the face, and much more rarely, apparently, than the best papers of any other foreign manufactory, a circumstance that proves that the paper pulp is prepared with extraordinary care, and that the paper is at least well pressed. The cause of the spots can scarcely exist, therefore, in the pulp itself. It probably arises during the period between the moment that the pulp is made into sheets and the time it is
delivered over to be albumenized. The spots, no doubt, are due to the use of the endless metallic plates that receive the pulp, or to the cylinders that dry the sheets, or those that polish them.

We believe that the last words of this research must be added by the manufacturer, who might be able to give an account of the vexing defects, either by instituting experiments, by examining the most prominent of the paper, which would lead, perhaps, to a recognition of the metal that gives rise to the spots. If it is brass, it comes from the endless metallic plates; if iron, from the cylinders; and if zinc, from the pressing of the material. Or there may be contact, in a manner that I cannot explain, between the back of the paper and metallic particles detached by the frames on which the sheets are placed.

[M. Davanne exhibited to the members of the French Photographic Society some examples of the spots, very much enlarged by means of M. Vau Tenne's reflectoscope, which permits of throwing upon a screen enlargements from opaque objects, such as a carte or cabinet photograph. This invention, which is certainly a very practical affair, has already been described by our Paris Correspondent.—Ed. F. N.]

EXTRACTS FROM A LETTER TO A YOUNG PHOTOGRAPHER.

BY ALEXANDER S. MACKAY.*

MY DEAR FRIEND,—According to promise, I now send you a few notes upon photographic art. You are aware that practically I have no knowledge of photography whatever, but as you have some confidence in my experience in my own business, I shall give you at random whatever occurs to me as having a bearing upon those subjects to which I am at all inclined. I shall therefore say a few words regarding schools of thought. Sir Joshua Reynolds, in his first discourse, truly remarks, "Every seminary of learning may be said to be surrounded with an atmosphere of floating knowledge, where every mind may imbibe somewhat congenial to its own original conceptions."

Let us see then, where this atmosphere may be most freely and advantageously inhaled. To those outside of the pale of art, picture galleries are fast becoming sources of art education; indeed, it is chiefly by such means that a knowledge commensurate with the growing desire for intellectual improvement can adequately be obtained. From the statistical accounts published from time to time, we see how largely those institutions are visited by the public. With, however, what complete catalogue does he know the extent to which many a person may learn, in a short time, of the art of his own and other countries. It is a gentlemanly thing to be able to say something of the painters of other days, both foreign and native, as well as of the celebrities of our own time. In the most of our large cities such places of resort are to be found, and, were they generally open in the evenings, would, no doubt, be largely attended by the more respectable of the working classes. The directors of those places should see to this.

To aspiring photographers there cannot possibly be better schools for acquiring the knowledge of those principles which to a certain extent govern their own art, and as such they should be highly commended.

To the followers of your art in Glasgow, such a school exists in the Corporation Galleries there, which contain many fine works, both in portraiture and landscape. To those of you whose inclinations lie towards landscape art, I should say that the study of such works of acknowledged reputation should evoke something of a spirit of inspiration. What I have often noticed as a defect in photographic landscapes is, their want of unity. They seem to be only sections of scenes. This, I believe, in most cases cannot be avoided, especially in subjects embracing a great extent of country. I have known landscape painters move from point to point—say a distance of thirty yards—to secure some object for the purpose of strengthening their pictures; it might be a mass of rock, or a stout old tree; this, in connection with the manouvering of lights and shadows, is often the means adopted for preserving the unity of their works. To make the trees, the rocks, and horizons blend, make the scene one within themselves. They give abstracts of truth, rather than total truth. This the camera cannot do; but it might at least be placed in relation to objects that would be valuable as foregrounds; and to have the power of balancing a scene with an artistic eye must be an important object, and our best landscapes might be often referred to with a view to obtaining that end. From the most famous galleries, you must allow me to allude to one by Sir Joshua Reynolds, which every photographer should examine as often as possible; it is that of Miss Linley, the mother of R. B. Sheridan. This is the "ceau ideal" of portraiture—perfect repose, superb breadth of light and shadow finely balanced, the background a darkness visible, out which looms the lovely head, composed of the most charming and passionate hues of rosette and purple. Such a picture, to a student of a little capacity, would suggest a photograph that would scarcely be surpassed.

Let me now say, happy should be the photographers who reside in Edinburgh, and who have the privilege of breathing the atmosphere of our National Gallery. We have here a collection of portraits by all the more distinguished masters, such as seldom can be seen, from Sir Anthony Van Dyck down to Sir David Wilkie, over a period of two hundred years. All the approved maxims of art in relation to portraiture are here expressed, from the broadest generalization of effect to that of the most infinitesimal and painstaking detail.

I had occasion, in a former communication, to refer to several of these productions, which, let me say, cannot be looked at too intently. Let me call your attention to two or three I formerly omitted. I would have you to look at the portrait of the late Thomas Duncan, R.S.A., painted by himself, which is perhaps the finest of all this painter's portraits (and he painted many very fine ones), as an embodiment of artistic power. This work has few equals, and it is remarkable for the absence of all meritless colouring; the round, well-developed head floats in an atmosphere of sober brown and grey; in its tone, indeed, it is not unlike a deep, rich, brilliant photograph, and may be looked at again and again with invigorating effect. Let me mention here that simplicity of arrangement and quietness of colour are unfailing sources of grandeur in this branch of art. Let us look at the whole length of Sir John Watson Gordon, by John Graham Gilbert. Here the full ensemble is complete. It is firmly the late President stands! How calm and dignified the expression of the head, which is admirably like the man! How powerful, yet subdued, the colouring! And all characterised by the most powerful finish. It has been remarked by eminent artists that there are few finer portraits, if any, in Europe. I shall only now allude to the dramatic half-length of the late Lord Murray, by Sir J. W. Gordon, which I also wish you to see. If space permit, I could point out many other noble works; but my object in this letter is to send you there to see for yourself, as to a school, where, by a little diligent attention, you cannot fail to be vastly benefited.

In the annual exhibitions of the Glasgow Institute of the Fine Arts, and the Royal Scottish Academy, are to be seen the best works of the present generation of artists, and you would act wisely in paying them occasional visits for the purpose of elevating your taste. In addition to the sources of education above referred to, I may state that there is a growing desire on the part of populous communities to have annual exhibitions of their own, consisting of paintings, sculpture, architecture, articles of

* Read before the Edinburgh Photographic Society.
vertu, and, in some cases, articles of manufacture. To those exhibitions our best artists are invited to contribute. Country noblemen and gentlemen are always willing to take an active part in such movements, and often send a few of their choicest pictures to give tone and character to the display. Let me instance the exhibition recently opened in the Smith Institute in Stirling, which was highly interesting, as being one of what is intended as a series of annual exhibitions. Here, and in the direct by Scotch and English artists, there were many erected by such gentlemen as Sir W. S. Maxwell, Bart., of Keir; Mr. Wilson, of Banknock; Col. Wilson, of Banknockburn, and many others, who have valuable collections, all of a deeply interesting and instructive nature. The enterprising town of Kirkcaldy, too, has already had two considerable exhibitions of highly respectable ability. Inverness and Aberdeen have likewise been bringing together the chefs-d'œuvre of their respective counties, I understand, with very great success. Now, in each of these exhibitions there must have been a good few pictures by the first masters, especially in portraiture. There are very few of our old baronial residences that do not contain many very fine family portraits. Renfrewshire towns, in Aberdeenshire as well as many by Jameson, Reynolds, and even a Vandyke may occasionally be found. Now, what I would wish to impress upon a photographer is the fact that the contemplation and study of such works, if he be at all a susceptible being, would tend to form a basis of good taste. Here are the works of men who have devoted many laborious years to their art, who have travelled through many lands for the purpose of becoming familiar with the masterpieces of other times, and who have not only caught their spirit, but in some instances have snatched a grace beyond them. It is good to have such pictures floating, as it were, in the mind's eye, that, in posing sitters, some regard may be had to pictorial effect. In none of these works will you find anything approaching to whiteness in the hair and hands: these are generally transmutable, of moderate depth, with the heads rising softly out of them. It is a fallacy to suppose that relief can be obtained by striking contrasts: delicate gradations, melting into the deeper shadows, will alone give it. By all means, then, avoid blackness and whiteness, or that feeling of solar action, which too many photographers have, and which are utter abominations to all who are not either perversely blind or obstinately stupid.

(To be continued.)

THE PROGRESSIVE RESULTS OF THE LAST SESSION.

BY JOHN NICOL, Ph.D.*

The photographic annals of 1874 are not difficult to write. The year has not been marked by great advance in any department: no wonderful improvement has been made, either in apparatus or manipulation; and hardly even has there been set up a claim for the introduction of a new process. Although, however, nothing very striking has occurred, there has undoubtedly been a continuous, steady progress. "Upwards and onwards!" has been the motto with which the whole body of workers have had before them, and the result is, a more general diffusion of the knowledge of both theory and practice of the art, and more general production of high-class work. In fact, there is nothing in which the progress is so visible as in the improvement which has taken place in the pictures produced by even the best photographers—a progress of the right kind, as, after all, the whole body of the ultimate object, and the object to which all our operations tend. This desirable object is being brought about mainly, I believe, in consequence of the fact that photographers are year by year putting less dependence on tools and material, and trusting more to the mind that uses them.

Although, however, there have been no particularly striking discoveries or improvements made, experimenters have not been altogether idle, and there are a few items of sufficient interest to profitably occupy our attention for a few minutes. Photography is largely indebted to photographic societies for its present position, and therefore I think the London Photographic Society may fairly be allowed first to claim our attention. During the early part of the year it passed its original charter. Here, an attendance nearly as possible stamped out of existence, not by enemies, but by those on both sides who loved it well. There was no doubt fault on both sides, as there generally is in all serious disputes, and it is a matter of congratulation that the breach has been healed, and that all seem now willing to work harmoniously for the general good. The Society has done good work in the past, and I hold it will have a prosperous and profitable future. I cannot help thinking, however, that a mistake has been made in seeking, by altering the title, to extend its influence beyond its fairly legitimate sphere. The merely calling it "The British Photographic Society" will not help much to make it what the name implies, while it may retard for a time the action of experimenters who are anxious to see the formation of a really national association—something of a federation—that will promote education or influence, without connection with any existing society, but supported by the members of all. I trust the members of the parent, to which all her true children have a filial love, will reconsider this matter, and have no doubt that they will come to see that, in the great city in which they dwell, they have a wide enough field for their operations, and that they will be ready to give their surplus energy in aid of the formation of a really national photographic association.

Colloidion-bromide seems to have passed from the domain of discussion, and taken its place amongst the recognized reliable processes. It has, however, during the year, mainly through the experiments of Mr. Bolton, been vastly improved. Some time ago it was found that by an emulsion free from any soluble salt could be made, and which simply required to be poured on the plate, and dried, to be ready for the camera. Subsequently Captain Fox suggested the addition of oleate of silver, and the process, thus improved, is, in my opinion, the most valuable addition to our knowledge that has been made during the session.

Dr. Draper, I think in 1872, showed us that we were mistaken in supposing that sodium was confined to the violet or blue ray, and during the past year Dr. Vogel has tried to show the conditions under which any of the rays might be made to act on a sensitive film. He found that when the film was stained with (say) a green, that the ray complementary to that, the red of the spectrum, impressed itself; and so in like manner with the other colours. This, like most new things, met with considerable opposition from various quarters, and both Dr. Monckhoven and Mr. Spiller wrote strongly against it, mainly on the always insufficient ground that they could not reproduce the effect. One at least of these clever experimenters has changed his opinion, and I think we have sufficient evidence to warrant the belief that there is something in it. If so, I have no doubt that the discovery is likely to lead to a method of combining colour with our films in such a way as to revolutionise our ideas of reproducing coloured objects.

Printing has, as usual, received considerable attention. Carbon continues to make steady progress, and prints by various methods are being daily produced, quite equal to anything that can be produced by silver printing. Considerable discussion has taken place as to the best means of removing the hypo from the paper, but the end of the matter is, in my opinion, that plenty of washing is the only safe and certain remedy for fading; the mischief causing the bluing of Mr. Dunmore, in the British Journal of Dec. 25th, to the contrary, notwithstanding.

Early in the year there was published a process by M
Willis, Jan., for the production of prints in reduced platinum, a process which would, I believe, give perfectly permanent results. The process is based on the fact that salts of platinum are reduced by oxalate of iron, and is as simple as ordinary silver printing. Why it has not attracted more attention I cannot understand, and am certain it only needs a trial to show its value.

In calling attention to a method of reproducing negatives by means of the dusting-on process, Herr Obernerter has earned the gratitude of all photographers, and its application, in the productions of backgrounds, or for composition printing, suggested by Mr. Werge, is likely to be extremely useful. Photographers are, however, a conservative race, and it may be some time before the process comes into general use; but I have no doubt that by-and-by no good or valuable negatives will ever be risked in the printing frame, but only used to make what may be fairly called an "Obernerter duplicate."

Gelatine has not taken the place that it was expected to do. Several operators succeeded in getting with it both fine and rapid results, but the emulsions were uncertain, and subject to rapid variation. To obviate this, Mr. Kennett hit on the idea of drying it into a pellicle, which needed only to be dipped in water and spread over the plate. He is foolish enough to carry the idea to the Patent Office, hoping, doubtless, to make a good thing thereby. I need hardly say that I am not sorry to hear that he has been so far disappointed, as if everybody who devises some trifling improvement in manipulation or material were to tie up his little dodge with patent tape, real progress would soon cease. The pellicle has not been taken, but is a good thing for all that, and I heartily recommend those interested in the matter to try it, assuring them that they are quite at liberty to make the pellicle for themselves, Mr. Kennett's patent notwithstanding.

This paper would hardly be complete without some notice of the work actually done as a result of processes and material. Time, however, will only permit of one single item; the Chinese "China," a bold effort successfully carried out in the production of the largest and best single work that has as yet been attempted. Most of the members of the Edinburgh Photographic Society have had an opportunity of seeing specimens of Mr. Thomson's work at the popular meeting, for which he was kind enough to give the pictures, and I am sure they rejoiced as fully as I did when they heard that the Queen had expressed her admiration of his work by giving him a gold medal.

Little that is new in tools has been introduced. The symmetrical lenses of Ross and Co. have met with much favour. They are, no doubt, very good, but I think their popularity is more a result of their small size, and the fact that they all fit into one flange. This is, undoubtedly, a move in the right direction, and will, ceteris paribus, give them a preference.

The only other thing of mark is Weston's Rotary Burnisher, and it really is astonishing how almost universal the use of this has become. Notwithstanding its absurdly high price, I have hardly visited a studio, in connection with which it was not to be found; and most of you know that down in the matter part of the year I have gone over a good deal of ground, and in every case the instrument was giving entire satisfaction. I have seen quite as good a surface produced in the ordinary rolling press with hot plates; but the simplicity of the burnisher, and the ease with which it can be wrought, has enabled it to almost supersede all other presses, at least for small work.

The year must bring this résumé to a close. From what has been said, it will be evident, that although no great thing has been accomplished, the year has not been barren of good results. A quiet, steady progress has been maintained, and there is abundant evidence that our much loved art is not on the wane; nay, that it is only step by step approaching that maturity which shall be of great things, and that all who either directly or indirectly lend a helping hand in carrying on the good work, have much to congratulate themselves on the present position and future prospects of photography.

NITRATE OF ALUMINA IN THE PRINTING BATH.

Mr. F. M. Spencer, writing in "Anthony's Bulletin," speaks in very high terms of the advantages of nitrate of alumina in the printing bath; but as the alumina nitrate is not in use in commerce, we think it necessary to give his experience and formula in its manufacture. He says:

"Dissolve pure white marble, or white chalk, in nitric acid to saturation; remove the excess of marble or chalk, whichever is used, and to the nitrate of lime thus formed add carefully of a saturated solution of alum until sulphate of lime be no longer precipitated; filter or carefully decant the supernatant fluid, and evaporate it to dryness, and you have, according to Mr. Anthony, a double nitrate of alumina and potass. It is a highly deliquescent salt of needle-like crystals, and requires a high temperature to produce crystallization in any reasonable length of time, being the most troublesome part of the operation. It must also be kept tightly corked in glass, to keep it from deliquescence by absorption of water from the atmosphere.

To make up a printing bath, proceed as follows:

<table>
<thead>
<tr>
<th>Substance</th>
<th>Quantity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Distilled, or ice-water</td>
<td>12 ounces</td>
</tr>
<tr>
<td>Silver nitrate</td>
<td>1 ounce</td>
</tr>
<tr>
<td>Alumina</td>
<td>1-8 to 1-4</td>
</tr>
</tbody>
</table>

"If the salts are pure, there should be no precipitate or milkiness when they are entirely dissolved. The solution will be an acid reaction. You must add sulphuric acid, hydrochloric acid, soda, potass, or ammonia, but in the following manner:

Dissolve a stick of caustic potass (in water) about three inches in length, and add carefully of any plain silver solution until a brown oxide of silver is no longer precipitated; proceed to wash this precipitate in many changes of water, lastly distilled or ice-water, until it passes off quite clear. Add of this oxide of silver to the silver bath in excess, and agitate occasionally for an hour or so; now add of liquor ammonia, a drop at a time, until a small amount of permanent precipitate of alumina is formed. This precipitate, together with the excess or oxide of silver, must be kept in the bottle with the silver bath when not in use. By exposing the latter to the light at all times when not in use, the bath is always ready for business. I would remark that the proportion of nitrate of alumina should be less for a heavy or double albumenized paper, as an excess causes the print to crack; but do not perpetrate the first blunder by using double albumenized papers. Float from one and a-half to two and a-half minutes, dry quickly, and fume as usual. Print but a shade darker than you desire the finished print, as little is lost in finishing, but must be printed before toning, as usual. Prepare a toning bath as follows:—Water, as much as required for toning once; stock gold solution, enough to tone well. Neutralize with an alum solution made by redissolving a precipitate of alum in sal soda by an excess of the soda, which should be always on hand, a pint being enough for several months. The bath should be mixed in a bottle, adding piece of litmus to the water, then the gold, and agitate; next add of the soda-alum solution until the blue colour is entirely restored after agitation, and your toning bath is ready for immediate use. Be very careful not to over-tone, and after toning return the bath to a bottle kept for that purpose only; for you have a perpetual toning bath, that only needs to be recharged, that with gold as above, is needed for use from time to time. Take care to collect the precipitate that deposits between times in a separate bottle, to be redissolved in aqua regia when the quantity of the precipitate becomes large enough to pay."
January 15, 1875.]

THE PHOTOGRAPHIC NEWS.

**I make my stock gold by dissolving a five-dollar gold coin, or its equivalent in English or French coin if I can get it, in C. P. nitric acid one part, and C. P. muriatic acid three parts; six drachms of nitric and eighteen of the muriatic being sufficient for the above quantity, and using a gentle heat to hurry the solution. A residue of chloride of silver (alloy) will remain as a precipitate, which does no harm; evaporate to dryness, being careful to lower the heat at the last; redissolve the dry mass in a little water and again evaporate, and redissolve in thirty-two ounces of water; add, drop by drop, of a saturated solution of bicarbonate of soda until the blue-green precipitate of copper (alloy) is all thrown down; filter out the precipitates, and to the solution add—**

</tbody>
</table>

The benefits of this printing formula I claim to be, in part, at least, as follows:—1st. A silver bath that does not easily become discoloured. 2nd. The preservation of the surface of the albumen paper, so that deep or much over-printing is avoided. 3rd. The albumen surface does not become soft or partly soluble in toning, involving little or no loss of detail. 4th. That the prints tone very easily with the minimum of gold. 5th. That the tones are deep and rich. 6th. The harmony of the several parts of the finished print, the economy of using a few prints. *I would remark, before closing, that the fixing and washing is performed as usual, and that should the printing bath become permanently discoloured, boil it, but do not attempt to precipitate the organic matter by salts or alkalies. Remember that all forms of soda, potash, or ammonia, except nitrates, precipitate the albumin in the bath, and it will not filter out. The above formula is the result of years of experiment applied to daily practice; and for many of the ideas I am under many obligations to Mr. Anthony. It has cost me both money and hard study; but I have got my pay back in knowledge, and I am saving the cost in practice. To the profits my fellow-photographers are most welcome, if they can succeed with it.*

**ENAMELLED CAMEO PHOTOGRAPHS.***

The cameo portrait is a vignett bust stamped up from a dark ground by means of a press, and possessing a glossy surface. The most difficult part of the business is the preparation of this brilliant surface; but it is by reason of this brilliancy that the pictures are so much sought after.

The most practical way of producing the finish desired is by means of the gelatining process I will describe. Another plan is to create the requisite amount of polish with a solution of shellac, but this method is seldom employed. By running the prints through a hot press the same glossy appearance may be imparted to them, and a rolling press recently devised by M. Muth fulfils the object in a simple manner. As, however, the price of the machine is rather high (about 150 marks or shillings), the usual plan of employing gelatine to render the portraits glossy will still remain popular.

The manipulations are very simple. Upon the negative is placed a suitable mask of black paper, with an oval opening of suitable size, and upon the reverse side of the negative is placed, in the usual manner, a vignetting glass, which must be much smaller than the opening of the mask. When a print has been secured, it is covered over with an oval of paper and the white margin of the print, which before was covered with the mask, is allowed to become deeply tinted.

The picture is then gelatined and further put into a press to be stamped up; but before this last operation is performed, the back is moistened with a little cold water and allowed to remain for about five minutes; unless this precautionary measure is taken the card easily becomes torn or twisted.

The glazing is managed as follows:—One part gelatine is dissolved in thirteen parts of boiling water, and this solution is then passed through a piece of clean flannel. A mixture is then compounded of:

<table>
<thead>
<tr>
<th>Component</th>
<th>Amount</th>
</tr>
</thead>
<tbody>
<tr>
<td>Alcohol</td>
<td>3 parts</td>
</tr>
<tr>
<td>Water</td>
<td>4 parts</td>
</tr>
<tr>
<td>Gelatine solution (above)</td>
<td>1 part</td>
</tr>
</tbody>
</table>

This is filtered in the same way through clean flannel, and both liquids are put away in well-corked bottles. To proceed to work, some well-cleaned and thoroughly even and perfect glass plates are selected, and these are coated with a thin layer of the glazing solution. The plate is then hung dry in a spot sheltered from the dust. When perfectly dry, the ordinary gelatine solution is warmed in a water oven, and a sufficient quantity to steep the photographs is put into a warmed porcelain dish. At the same time the bottle containing the "alcohol-gelatine" is put into hot water, to render it fluid and to clarify it. In very hot weather, be it known, the gelatine solution remains fluid, but then assumes a milky turbid character. When it has been clarified, the collodion plate is covered with the mixture, the superfluous liquid being allowed to run back into the bottle, and the plate is then put on one side for two or three minutes. Then the plate is coated again, but this time with the ordinary gelatine, and then the surface is thoroughly drained by laying it on the plate drying bench.

During this time the print itself is dipped into the gelatine solution contained in the porcelain dish, care being taken in the operation to prevent the formation of air-bubbles. After the plate has been coated a second time with gelatine, the print is taken out of its bath, laid down carefully by the bottom margin, and then gently lowered, so that the whole surface comes into contact. In this way the gelatine is forced upwards as the print is lowered, and then may be easily removed with the thumb-nail. When, however, bubbles are formed in the middle or at the sides of the picture, their removal does not involve the least difficulty. When all the bubbles have been destroyed the picture is pressed slightly with the fingers and placed to dry.

The mounting of the pictures is done in this way. After the picture has been dried somewhat on the collodion plate—that is to say, after a period of three-quarters of an hour, or double that time—it is coated lightly with good fresh paste, and upon it is laid a card, which is also faced with the same material. The cards should be soaked in water for half-an-hour before being used, and pressed in the folds of a towel just prior to the starch being applied. The paste is laid upon the print and finished off with the hand, and afterwards a glass plate is put upon it to press it down and keep it in contact, a stone or weight of some kind giving more pressure. In this position the card remains for some twelve to eighteen hours in order to dry spontaneously. When perfectly dry the blade of a penknife is pushed underneath the picture, and it is lifted from the glass.

The photograph should leave the glass plate very readily; if this is not the case, either the gelatine solution was too thin, or the mount and picture are not sufficiently dry.

**THE Imitation of Lace on Silk by Photography.**—The *Scientific American* says:—"A new and beautiful application of photography has lately appeared in England, by the aid of which any lace design can be transferred to silk, so that the latter material appears to be covered with the delicate and costly fabric. The lace to be copied is secured in a frame in contact with sensitive albumenized paper, and exposed to the light until a very deep impression is obtained. This is then fixed, and the paper, washed and dried, forms a perfect negative. Another piece of paper is then sensitized with bichromate of potash and gelatine and exposed under the former. Inking with India ink, the negative is then placed in water and lightly rubbed with a sponge. This throws out every detail of the inked spaces, the rest remaining white or free from ink. The impression is lastly transferred to a lithographic stone, and thence printed upon the silk by the usual process.

NEW AIMS FOR THE PHOTOGRAPHIC SOCIETY.

The paper on the origin, aims, and achievements of the Photographic Society, with suggestions for its further development, read before the Society on Tuesday evening, by Mr. R. D. Nickson, addressed itself to all photographers, whether hitherto connected with, or concerned about the doings of, the Society, or not. The chief purport of the paper is to make a bold claim for a higher position—to demand for photography Government recognition and aid, not simply as a favour, but as a legitimate guardon for the services the art has already rendered to mankind.

Tracing the history of the Society from its origin in January, 1853, with Sir Charles Eastlake, the President of the Royal Academy, as the President also of the new Society, devoted to the youngest born of the arts, down to the present day, he finally suggested certain steps for its further development. These are, first, that a Royal charter shall be obtained for the Society, that it may "thus possess the power of granting diplomas for merit;" second, that the claim of the art to Government aid in the form of a grant and preference should be preferred; and, third, that a system of appointing committees for the purpose of making special investigations be adopted.

There can be little doubt that each of the ends proposed, so far as it is tangible and possible, is desirable. The latter part of the address has been specially interesting, at any time when it may choose, without extraneous aid. The two former propositions, we are compelled with regret to admit, are, besides being somewhat vague, at present ill-timed. The Society has scarcely yet thoroughly recovered from a state of disarray which, to say the least, did not increase its prestige in the scientific world, and any application for grants of money from public funds might possibly be met with a suggestion as to the wisdom of the Society acquiring perfect harmony within itself before asking for the control of public money.

In glancing back at the history of the past, it does seem a little surprising that no effort was made to give the Society status by obtaining a Royal Charter. It began modestly enough, and for many years retained its success. In its early years, there was a feeling on the part of many, and for many years retained its success. Her Majesty the Queen and her Royal Consort were its patrons; Sir Charles Eastlake, Sir William Newton, and the Chief Baron of England were in succession its first three President; many of the nobility were amongst its members, and men highly distinguished in science and art were on its council. Its funds were large, and all its prospects auspicious. Photography became more essentially a branch of commerce, it became more fashionable, and the merely dilettante members of the Society fell away. Gradually, also, the Society became.

impeccuous, and got finally into monetary difficulties. A variety of causes tended to bring about this result. The first serious fiscal error consisted in taking permanent premises in Coventry Street, at a cost the Society was not able to maintain. This error was not likely to be repeated; but there were a number of other sources of loss, the memory of which should not be ignored, as they are still possible sources of danger. A society with small subscription, like that of the Photographic Society, may very easily get into debt. One source of loss to the Society which aided in bringing about its difficulties was the" Petition" upon which exhibit had been previously amended to nearly a hundred pounds. There is some danger even now in the same direction. The first two or three of the exhibitions revived a few years ago did not tax the funds of the Society at all, or very insignificantly; whilst the last exhibition has, we believe, cost the Society more than any of the new series of exhibitions. The losses of the Society were a heavy item of cost, and were abandoned on that score. Mr. Hooper, we notice, practically suggests their reumption. At present, and for many years, the Society has not held any soirees, the informal re-union of members and their friends at the opening of the exhibition being specially arranged to avoid the character of the soirees proper, which would necessarily involve a larger room, extended arrangements, and increased cost. But the Society has appointed scientific committees for investigating special subjects, and a considerable cost was incurred to the Society by their labours. In the committee proposed by Mr. Hooper, especial care must be taken to avoid a repetition of the same error. There were some other sources of loss to which we need not further advert now.

To return to the charter. It is not under the energy and spirit of Mr. Glaisher and the council who assisted him, the Society worked through its difficulties, discharged its debts, and acquired a state of honourable solvency again. But one source of regret accompanies the recollection of the effort then made, and it is one, we think, which must be felt by every member of the Society: it is, that circumstances should have arisen to compel Mr. Glaisher to retire from the presidency just at the period when the effort, for which he had so strenuously laboured, the absolute freedom from debt of the Society, had been accomplished, and the position of the President promised to become one of comparative comfort and honour. Should it please the members by their votes to recall him this year to office, there is no doubt that his friends and admirers would welcome him probably none would do so with more complacency. For an estimable and amiable gentleman who has during the provisional government of the last six months filled his office.

To return for a moment to the propositions of Mr. Hooper's paper: the first objection to the plan of obtaining a charter is that of cost. The precise amount necessary we cannot with certainty state, but we believe it would involve an expenditure of a few hundred pounds, which the Society does not possess; and it becomes a serious question, if it had funds in hand, whether they would be well expended in such a manner. The chief aim seems to be to enable the Society to grant honours, or, as Mr. Hooper phrases it, "diplomas." There appears to be some vagueness in Mr. Hooper's ideas on this part of the subject. The possession of a charter of incorporation would involve such powers as those to which he refers. It would involve no such thing as to grant diplomas. Diplomas are granted by various colleges to those who have gone through a prescribed course of study, and passed a prescribed examination; but the various chartered learned societies—such as the Royal Society, the Society of Antiquaries, the Chemical Society—possess no such powers, and exercise no such functions. The idea of the kind of diploma which has hitherto been custom has obtained of indicating a given proclivity and a certain culture by the use of the honorary letters indi-
cating such fellowship. To render such a plan admissible would render necessary some change in the constitution of the Photographic Society. At present any reputable gentleman interested in photography, but without possessing any knowledge of it, is eligible as a member of the Society; but in societies where admission involves a fellowship, some guarantee of qualification and fitness is generally imperative, and the honour would be valueless without it. The suggestion of a charter, the granting of any of the a certificate of merit, or "diploma," could at any time only follow a course of study and due examination, and the possession of a charter is not necessary to enable the Society to adopt such a course if it see prudent.

In regard to grants of money, there can be no doubt that the Government is indebted in various ways to photography for increased efficiency and decreased cost in various departments; but it might be asked, what special claim the Photographic Society had to represent photography in asking for money? Grants of money to learned societies for general purposes are not commonly made by the English Government. Assuming that the plan of appointing committees to undertake some especial branch of research for the prosecution of which money might be most appropriately employed, is not improperly looked for, and might possibly be received through a regularly organized channel. Mr. Hooper quotes a passage in which allusion is made to the yearly grant made by the Government to the Royal Society. There is some slight misapprehension about this. There is a yearly grant of one thousand pounds made by the Government to aid in the administration of the Royal Society, not for its own purposes, but for the furtherance of science in various ways. The amount is apportioned by the Royal Society to such purposes as may best promote scientific progress, and possibly if a committee of the Photographic Society could make good its claims, it might receive some share of such a fund. Money grants in any other form from Government sources are generally scarce. It is very doubtful if the usual premises for the meetings of the Society will be seen much more regularly than at present. Many of the learned societies have already free quarters at Burlington House, and the Photographic Society has, we think, a good claim. The late Chief Baron, whilst president, expressed a hope at one time that he would shortly succeed in securing such a boon, but his death intervened, and his successor has not also hoped for success in a similar effort. Unfortunately, personal influence is necessary, as well as a just claim, in such matters, and at present, so far as we know, the Society lacks such influence in its representatives.

With the aim and spirit of Mr. Hooper's paper it is impossible not to sympathize warmly, and we cordially concur in many of his remarks. The only question which arises is, whether he does not aim at too much, and at a wrong time, to secure a success.

A NEW PHOTOGRAPHIC LIGHT.

An artificial light, new in its proposed application, which it is probable may be found useful for photographic pur-

poses, was exhibited at the meeting of the Photographic Society on Tuesday evening last. Mr. Spiller's object had been to devise a light as rich in actinic rays as possible, involving less trouble, cost, and risk than attended the various artificial lights which had hitherto been proposed and applied in photography. The electric light and the oxyhydrogen are cumbersome and costly; incandescent mag-
nesium is costly, and the dense fumes emitted are inconvenient; the recently proposed lamp to be supplied with nitric oxide and phosphide of carbon is attended with risk; and some others have each specific inconveniences. The light proposed by Mr. Spiller is derived from nitrate of potash and sulphur. When nitrate of potash is submitted in a capsule or flask to the heat of a spirit flame, somewhat beyond the point of fusion, and a succession of small pieces of sulphur introduced into the fused nitre, it bursts into a brilliant white flame of dazzling intensity, resembling or exceeding that of phosphorus in oxygen. One part of sulphur to three, or a little more, of dry salt-
petre is consumed in the process. Only half the normal amount of sulphurous acid evolved in the combus-
tion is given off in fumes, the remainder being held in the residue, and there are no solid particles given off in the fumes. The mere cost of the material is comparatively small, that of the sulphur and nitrate of potash necessary for maintaining a very intense light for ten minutes being about one halfpenny; but the wear and tear of apparatus in producing a flame of intense heat remain to be esti-

mated. The mode of maintaining a constant light, and the best means of making it practically available in photo-

graphy, must also remain matter for further experiment.

MONCHKOVEN'S NEW DEVELOPER.

Dr. Schnaux, of Jena, has analysed the new iron de-

veloper of Dr. Van Monchkoven, which, that gentleman states, is composed of water, glacial acetic acid, and pro-

tosulphate of iron, heated for some time to 100° Cent. Dr. Schnaux makes the following report:-

The dark brown color of the liquid at once proved the presence of acetate of iron. The decomposition of a solution of this salt takes place, however, at a tempera-

ture of 50° Cent., with the separation of hydrated oxide of iron and development of acetic acid fumes. The fluid filtered from the developer appears, when all oxide salts have been decomposed, no more of a light green color, signifying a freshly prepared solution of iron from iron oxide. It behaves differently to the latter, and, after being separated again, another development of acetic acid takes place, together with a separation of oxide of iron, the latter being of a much darker kind than formerly. All this points not only to the presence of acetate of oxide of iron, but also to that of ferrous acetate. That the latter could not have been produced by the lengthened action of the glacial acetic acid upon the sulphate of iron is clear to any chemist, for the far stronger sulphuric acid will not allow itself to be separated from the ferrous oxide, the presence of a base being necessary to such a result. In a much shorter and more successful manner could the double decomposition bring about the formation of acetate of ferrous oxide, namely, either by the addition of acetate of ferrous molybdate, in which case the iron would have separated with the base as an insoluble salt, and been removed by filtration. Formulas for preparation of acetate of iron are given in many editions of the Year-Book of Photography.

An examination of the crystals separated from the sulphate of iron proved that no sugary sulphate nor iron ammoman compound was present. On the other hand, on heating the dry residue which remained after evaporation of a sample of the developer with caustic potash, strong evolution of ammonia took place. The presence of a compound containing nitrogen—not in the form of am-

monia—was therefore proved. In seeking for this material, a large series of experiments were instituted (which I will not here describe) for the purpose of separating as well as possible all the iron from the solu-

tion without introducing at the same time foreign bodies in injurious quantities.

Of the nitrogenous bodies which might be used in a developer may be cited morphine, albumen, and gelatine. Albumen, if present, would have been separated during the process of boiling, and for this reason there was no necessity for looking for it. Moreover, albumen added to the solution only separated sulphate of iron. No trace of morphine could be detected in the alcoholic residue. On the other hand, the aqueous solution, after oxidation and precipitation of all the iron, gave a strong reaction on
the addition of tannic acid. This produced a strong, tough, and yellowish-white precipitate, which, nevertheless, was separated in the perfectly neutral solution, so that, on the addition of a solution of tannin, it was necessary to put in either a trace of ammonia or of some mineral acid, such as hydrochloric or nitric acid. This tannin precipitate, when filtered and washed, proved, when heated with potash, to contain undoubtedly a quantity of nitrogen. It may be concluded, therefore, that glue or gelatine is contained in the developer in question. At any rate, a body is present that contains nitrogen.

HOW TO UNVARNISH NEGATIVES.

BY FRITZ HAUKER.†

It sometimes happens that a negative, after it has been finished and varnished, appears too thin or thick for printing purposes. To improve such a cliché, it is best to remove the film of varnish, in the first place, and then to treat it again with a solution of one kind or another, to bring about any change in the character of the silver image that may appear desirable. The most certain and simple method of proceeding, I believe to be the following:

The negative in question is in the first instance moistened with alcohol, by pouring this over the varnished surface two or three times, so that the latter becomes thoroughly softened, and then the negative is immersed in a sufficiently large bath filled with a solution of ammonia. The cliché is dipped into the liquid and lifted in and out with a hook until all signs of greasiness have disappeared from the surface. When this happens the negative is taken out of the bath altogether, and washed carefully with water.

It is then quite free from varnish, and the film may be strengthened or weakened according to circumstances.

If the film is to be intensified, then this may be done either by means of iodine, pyrogallie acid, or bichloride of mercury, as may be deemed best. To weaken the film, a cyanide of potassium solution, and one of bichloride of mercury, may be made use of. You proceed by pouring over a plate, in the first place, a weak solution of mercury (say in the proportion of one part of the mercury salt to twenty parts of water), and this is allowed to act upon the image until it has assumed a slaty grey colour. Then the plate is carefully rinsed with water several times, and a strong cyanide of potassium solution poured over it. If the cliché is not sufficiently weakened by one operation, it may be repeated a second or third time in exactly the same manner, without any fear being entertained for the image.

FIXING SULPHOCYANIDE OF AMMONIUM. V. HYPO.

Sir,—In confirmation of Mr. Durand's experience, in your current number, I may state that I have in my possession some prints toned and fixed with sulphocyanide of ammonium which, hung upon a damp wall, and constantly exposed to light, are unchanged after twelve years of existence; whereas other prints, fixed with hypo at the same period as the above, have been (of course incurably) afflicted with the jaundice within a year after their removal from the washing trough.

I ought, however, to add, that after (for an amateur) a considerable experience of sulphocyanide of ammonium, I cannot claim inventive success from its use, and I have even known that a batch of prints toned and fixed in the way quite equally—that some appear indestructible after years' wear of a year, while others in a short time have fallen into "the sere and yellow leaf," young in years, but old in affliction—"I am, sir, your obedient servant.

CORNHILL, 8th January.

H. J. C. ANDREWS.

SECRET PROCESSES.

Sir,—As the question of secret processes is now before your readers, I would like to make a few remarks on the subject.

I would suggest to the profession and to amateurs, before entertaining any secret process that may be advertised, to refer back to the journals, and see what has been said by correspondants on the subject that has been advertised as a new and secret process, and give what has been said a fair trial before buying a secret process; and if, after a fair trial, they fail, I would then recommend them to apply to the process-maker, and if, after paying the fee, they find out that it has been published before, let them be contented.

I have heard more than one person complain that a process sold as new for making enlargements turned out to be almost as old as the original collodio-albumen process itself, and they felt annoyed that they had paid for what had been published years before. This was no fault of the vendor. They should have looked into matters, and given what had been published a fair trial before they had parted with their money. The vendor in question seems to have been the first to apply the slightly modified collodio-albumen process to the purpose of making transparencies for enlarged negatives, and, having been the first to exhibit pictures done by that method. Although the modified collodio-albumen process had been used for the purpose of making transparencies for other purposes years before, it does not seem to have been applied for the purpose of enlargements until brought out by that gentleman referred to for that purpose as a secret process.

As the treatment of the nitrate bath is known to attract the attention of all photographers, I would like to invite all those who feel disposed (and I believe there are many of that class) to give their experience on the best method of preventing stains and pinholes in the negative, without boiling or sunning, as to avoid these appear to be a point that Mr. Edwards, in his recent announcement, seems so desirous of avoiding. In that I agree with him, and I believe that boiling in alcohol is invariably beneficial, as it is never certain in its working after.

I am one of those lucky fellows who have not been troubled with stains or pinholes in their negatives for many years.

Mr. Bingham told me—"I think as far back as 1857—how to avoid stains and pinholes, and I havenever been troubled with them since. Therefore nothing now in the method it has been published over and over again. No boiling or sunning is required. I am almost ashamed to state the method again, as I have said, it has been so often published. However, as I have invited others to give their experience in avoiding stains and pinholes in the negatives, I will give mine. We will suppose a bath has been made..."
Those using this method will never require to buy a secret process. It will be seen that I am not speaking from a few weeks' experience, but from eighteen to twenty years, and the method has never failed. -I am, sir, yours respectfully,

George Willis.

Dear Sir,—I do not often trouble you with a letter, but I wish now to endorse Mr. Edwards's suggestion in your last issue, that a small committee to report upon new processes would be a great acquisition to practical photographers, and to the busy photographer especially. It has long been a favourite idea of mine, and it has often occurred to me, how much the value of your paper would be, if you could see your way clear to give us an impartial opinion of some of the secret processes in the market, as well as the result in your own hands, of many of the recent claimants for favour of dry plate and other formulae. What a world of useless individual experimenting would be saved by one efficient person doing the work once and for all!

Of course, you would have to look the fact in the face, but if your opinion were adverse, your publisher might scarcely reckon upon a full page advertisement afterwards; but for my own part, I should be glad to double my subscription to assist in averting the fearful consequences of such a calamity.

I have no objection whatever to pay for the advantage of additional knowledge, if that knowledge be actually of interest; but the point about secret processes we want to know—how much reality, and how much humbug for the money; and it is this that should be subjected to the perfectly fair and candid criticism of two, three, or four gentlemen whose names would place them above suspicion, and who would not be afraid to speak out; and amongst them I would suggest that the editors of the two journals should find a place. Funds for the purpose of experiment, &c., I think would soon be forthcoming, and I hail Mr. Edwards's suggestion as an eminently practical one, and one that, carried out, would enhance the value of the journals indefinitely. I remain, dear sir, yours truly,

B. W. Parsons.

[We give insertion to Mr. Preston's very candid expression of opinion, and fully agree with him as to the advantages and comfort to purchasers to have some authoritative assurance in regard to purchasers. But a little reflection may make us see that the responsibility involved is one that no individual ought to be expected to undertake, and which no individual could possibly satisfactorily discharge. We have said repeatedly that, in every case of which we have certain knowledge, secret processes offered for sale are processes which have, in the main, been already published, and the advantage obtained by purchase consists simply in being saved from that endless experimenting which our correspondent deprecates. The process-seller has probably undertaken that, and sells the best, or it may be a combination of two or three of them; and purchasers generally buy on seeing results. The secret process which, when purchased, may prove a boon to one photographer who reads little, and give him the highest satisfaction, will disappoint another, who complains: "Oh, I have seen that in the journals!" He has probably seen it, but has not tried it; or he has tried it without sufficient care and patience, and feels not only mortified that he has paid money for it, but that some one else has achieved the success which he might have had. The purchase of secret processes is very similar to the purchase of lottery tickets, and those only who are prepared for blanks as well as prizes should invest therein. We doubt very much whether we could find time to investigate such matters and take the responsibility of endorsing them; but it is certainly not the business of the Editor of a journal. His duty is to give the fullest information he can obtain, but certainly not to accept the responsibility of pronouncing ex cathedra upon such matters. The loss of advertisements to which our correspondent refers on the one hand, would be a small matter to the amount of obstruation the Editor might expect if he endorsed as worthy a process with which some purchaser was unable to succeed.—Ed.]

PRODUCING ENLARGEMENTS.

Sir,—Notwithstanding the great strides made during the last few years by parties who have made photographic enlargement their study, I think it will be admitted that there is still wanting the most important process by which small photographers who have scarcely any demand for large finished pictures might supply their sitters with pictures of a size suitable for framing. I fully admit that for those who can obtain orders for such work, it is a good (perhaps the best) plan to send it to be done to some house where they can rely upon having it well executed at a moderate price; but there are many who, like myself, only at very rare intervals receive orders for such work, but who might add considerably to their income had they the means of making themselves a good plain enlargement from a carte-de-viete negative that is much liked to (say) whole plates, or ten by eight, or, in some cases, even to cabinet size. I myself could not afford to send such work away to be done, as the probability is that if it was done it should not prove (without the giving of an order), it would not then prove a remunerative proceeding; while if it could be done by the photographer himself, he would, in the event of his picture not being purchased, only lose his own time and materials.

As to the means by which this object can be attained, I am, as a reader of the News, quite aware that some sort of system has to be produced, by means of the wet collodion process, an acceptable plain enlargement. I have tried it with great care, and must say that I have not succeeded in doing so. Others are advocates of the albumen process; and here, again, I have not succeeded to my expectations, although I think I brought to the work some degree of patience and perseverance. I do not stand alone here, for I know those who paid a good price for the process when introduced, but who have thrown it on one side on account of its difficulties. I think its warmest advocates will admit that it is quite an undertaking to prepare a batch of plates, and that they do not leave their ordinary work with any great avidity to commence the task.

With the carbon process I have no experience, and should be glad if you or any one of your readers would give me any advice. I am always ready to give his experiences for the benefit of others, would be good enough to give information as to the production of carbon transparencies, as I see by the News that he is working the Lamberttype process. I am, sir,

A Provincial Photgrapher.

REMOVING STOP DURING EXPOSURE.

Dear Sir,—May I ask space for a few words as regarding removing the stop during the exposure which I read in the News a short time ago, and have found it a great boon. I took a view the other day, which was rather dull here, with a rapid rectilinear lens, and gave it eight seconds, taking out the stop No. 3 at four seconds; developed, and found it exposed quite enough. I tried the view without taking out the stop, and gave sixteen seconds with the same lens, and found it under-exposed. I have also found it a great boon in taking portraits. Apologising for trespassing on your valuable space,—I am, dear sir, yours truly,

Graffen Underwood, Kettering.

C. R. C. Vernon.

Proceedings of Societies.

Photographic Society of Great Britain.

The usual monthly meeting of this Society was held in the Architectural Gallery, Conduit Street, on the evening of Tuesday, the
The Chairman briefly called attention to the steps necessary for the election of officers. All the officers would on this occasion retire, and would all be eligible for re-election; and their names would therefore, in accordance with the rule, be printed on the ballot papers. Every member was at liberty to nominate other candidates, but their nominations must be sent in to the Secretary before that day week. Auditors and scrutineers having been duly appointed,

Mr. Spiller asked Dr. Mann to occupy the chair for a few minutes, as he wished to exhibit to the members a new light reflecting power. Mr. Spiller proceeded to demonstrate and produce a light of remarkable purity and intensity. He also exhibited some fine transparencies printed in four seconds, the plate being held at a distance of one foot from the light.

A vote of thanks having been passed, and an intimation made by Dr. Mann that a slight modification of the rule relating to the certificates of members would be proposed at the annual meeting in the next session, Mr. Frew assumed the chair.

Mr. Hooper read a paper on the "Origin, Aim, and Achievements of the Photographic Society, with Suggestions for its Further Development," which will appear in our next (see Leader).

The Chairman said the paper was full of suggestion. Many of the ordinary members considered that it had been written at different times before—the question of a charter, for instance—but as it would involve a serious cost—how much he was uncertain—

Mr. Davenport: About £400.

The Chairman added, they were not rich enough to attempt it, and any resolution on the subject would be, he feared, premature. Then as to a grant of house accommodation: attempts had before been made to secure rooms in Burlington House, but, unfortunately, all the space had already been appropriated. Then as to the question of Chiswick: in a profession like medicine, where health and life were entrusted to a professional man, it was necessary that the public should have such a guarantee of fitness as the diploma of a college and properly constituted body of authorities could give; but it was not customary in other professions, and he scarcely saw its applicability to photography. However, the questions were open for further consideration and discussion.

Mr. Davenport corrected some errors of date in the paper. Referring to the history of the Society, he said that circumstances had changed much during the years which had passed. At the time the Society originated, photography was not recognized as a science; now it was rather an industry. The Society at first was at no charge; its quarters were at the Society of Arts; it had an honorary secretary and a remunerative journal. It was not until the Society grew proud, and insisted on separating itself from the Society of Arts, that its responsibilities and difficulties began. Then began also the struggle between commerce and science, commercial men striving to ignore the scientific claims. Science had, however, done more for photography than ever photography had done for science.

The Secretary (Mr. Friswell) pointed out some errors in relation to photography and astronomy. The first solar eclipse in which photography took part was in 1860, when an expedition under Mr. Warren de la Rue photographed the eclipse. In relation to which Mr. Hooper read a paper by Mr. Lockyer and Col. Tennant, there was some confusion in the paper. The expedition to observe that eclipse under Mr. Lockyer, in which he himself had the honour to take part, had no photographer attached, but Lord Lindsay had undertaken some photography, Col. Tennant, being in India, had also made some photographic observations.

Mr. Bird said that he was afraid that photography, as photography, was out of court for Government claims. It was a compound art science. Mathematicians and chemists alike had combined to make it, and they received their own recognition. Whether a charter would be of sufficient value to justify the trouble and expense was, he thought, doubtful. If there were any chance of obtaining any kind of Government recognition, it would of course be desirable; but he should like to know if there were any chance before assuming the position claimed in the paper.

The Chairman said that in the British Association photography, as photography, had no definite standing, because some subjects connected with it came naturally into Section A, with physical science, and others into Section B, with chemical science.

Mr. Walter Neil Hartley agreed with the Chairman, and said doubtless if, in any specific investigation in which the Photographic Society were engaged, it could present a fair claim for aid, a grant would be made by the Royal Society.

The Secretary said that the Chemical Society had a charter of incorporation, but it had no power of granting diplomas, nor had any other similar society.

Mr. Stillman said that, practically, all the science in photography was in chemistry.

Mr. Frew, referring to the British Association, said that many papers had been read by Mr. Claudev and others, but always in one of the sections fitted for the special subject. He believed also that grants had been made by the Association to aid some of the members of the Photographic Society.

Mr. Bart did not think a charter would materially aid the Photographic Society.

Mr. Hooper said he thought the time for discussing his paper had scarcely arrived. When its propositions had been more fully contributed to, he should be glad as he could.

The proceedings then terminated.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The third ordinary meeting of the season was held in 5, St Andrew Square, on Wednesday evening, the 6th, the President Dr. Thompson, in the chair.

The minutes of the previous meeting were read and passed, and the following candidates were balloted for and unanimously elected as ordinary members:—Messrs. W. Home, James Steele, W. Haldane, W. H. Davies, Jun., Charles Robb, Richard Brown, John Weir, and A. Cormack.

Dr. John Nicol read a paper on "The Progressive Results of the Past Season" (see page 26).

Mr. W. Nelson said that Dr. Nicol was much too modest in his introductory observations: the paper was really an admirable resume of the work of the year. He was not at all sorry that there was nothing new to record. It would be much better for the Society if members worked all the year round and brought something good, rather than something new. He was sorry that there were many great guns who never fired a shot, just because they thought what they knew was too old. They should remember that the greatest temple was built of single bricks, and every man should contribute as many bricks as he could.

Mr. Turnbull thought the introduction of Ross's symmetrical lens the greatest hit of the year; he should very much like, however, that a similar lens of much longer focus were introduced, as it would be of the greatest possible use, and hoped the firm would look into the matter. The rotary burner did no duty in its work, it was very well, but not better than any ordinary press with hot plate. Photographers had in their possession the means of glazing their pictures before the burner was introduced, if they had only taken the trouble to do it.

Mr. Barlow was much pleased with Dr. Nicol's paper, and should look forward to getting it printed in the journals, where it could be read at leisure. He quite agreed with Mr. Turnbull respecting the burner; it was a capital tool; but he had seen as well, if not better, work done by the ordinary press and hot plate. He had repeatedly tried the burning-on process in reproducing negatives, and found it exceedingly simple; he considered it one of the greatest discoveries of the day. Not only could an exact copy of a negative be made, but a faulty negative could be vastly improved in the reproducing process as well.

Mr. Alexander Mackay then read a paper entitled "Extracts from a Letter to a Young Photographer" (see page 26).
Mr. Asher could not agree with Mr. Mackay in his estimate of the Rembrandt effects, if it applied to such as those which he (Mr. Asher) had laid on the table for the inspection of the members. They were principally of American production, and were sent for by the Society editor of the Photographic News, in a letter an extract from which he read, as "fair examples of the legitimate use of shadows and half-shadows." He would like much if Mr. Mackay or Mr. Boss would point out any defects that they might see in the specimens, and say how they might be remedied. He also took exception to the epithets "trash" and "vulgar" that had, according to the report in the journal, been applied to the effects in question at a previous meeting of the Society; and Mr. Boss explained that he used the word rubbish, not vulgar (laughter). Mr. Baeremon said that Mr. Asher had mistaken his meaning. In his paper, read at the meeting referred to, he used the word "vulgar" in connection with the name, and not with the result itself. He could not say much in favour of some of the pictures on the table, however. The fact was that the effects were produced by a false reflected light—probably by the hand-screens introduced, by Mr. Kent—and the result was the production of lights thoroughly untrue to nature. He could not agree with what had been said against retouching. Photographs were once used, and a little retouching was often absolutely necessary to make their work as near truth as possible. Mr. Nelson thought the pictures exhibited by Mr. Asher were very pretty, but nothing more. They were undoubtedly retouched, or so lighted that all texture was destroyed. Mr. Asher retouching in this day and age was the dislike that some members had was more to the same than to the results, which, in his opinion, were very beautiful. They might not be like Rembrandt's work, but the name was selected as a matter of convenience, and any other one would have done as well. He should be very glad indeed if every member of the Society could produce work equal to that on the table.

Mr. Boss could not understand what Mr. Bashford meant by saying that retouching was necessary because of imperfect tools. Did ever anybody hear of retouching a Daguerrotype? Yet not a hint of retouching was the perfection of photography. Mr. Bashford was extremely glad that its re-introduction had recently been recommended in influential quarters, and hoped that the recommendation would be largely acted on. The result, he said, those pictures on the table very fine specimens of what photography could do. Each old master had managed his light as he thought best, and it did not do justice to the amount and effect. And the same might be said of photographers. The one thing needful was the cultivation of the very possible methaesthetic education, and when that was accomplished there would be no need of the kind of work that would be turned out, no matter by what name it might be called.

Votes of thanks were given to Dr. Nicol and Mr. Mackay, and the meeting adjourned.

Photographers' Benevolent Association.

The first Annual General Meeting, followed by a Vocal and Instrumental Concert and Exhibition of Lantern Slides, was held on Monday last, at the Co-operative Institute, 55, Castle Street, Oxford Street, Rev. F. F. Stratton in the chair. A large assemblage of photographers and friends were present. A large collection of fine photographs—the prizes in the Art Union Distribution shortly to be held—was exhibited, including a portfolio of autotype prints, upwards of thirty in number, comprising the first prize; two 36 by 24 framed autotype enlargements; two on the Thames; three 18 by 24 enlargements, by Mr. E. J. Edwards; forty superb landscapes, by Mr. W. Bedford; a splendid collection of statuary, by Mr. England; a copy of "Rebecca at the Well," by Mr. Blanchard, of which subject twelve copies have been given to the Association by Mr. Blanchard; the large photograph entitled "The Spring," by A. Ford Smith; and contributions from a score of other gentlemen.

After some suitable remarks from the Chairman, the Secretary read the report of the Board of Management as follows:

Mr. Chairman, Ladies and Gentlemen,—

In presenting this the first report of our labours on your behalf, we trust that a short account of the establishment of the Photographers Benevolent Association will be of interest to the members and photographers.

It is now nearly eleven years since Mr. A. H. Wall read before the South London Photographic Society a paper upon a Provident Fund for photographers, in which he urged upon the profession the desirability of, and the benefits accruing from such fund; and, to show the serious nature of the matter, he quoted the opinion that such an Association should be formed; but after a correspondence in our usual place (viz., the journals) the subject dropped. Since that time it has cropped up again at various meetings, and the subject was forced upon the attention of the profession by a record of details connected with the sufferings of brethren in distress. Each time, after correspondence containing suggestions as to what other people ought to do in the matter, the subject dropped. In 1885, during the usual discussion, a well-known gentleman (Mr. Matthew Whiting) made some excellent remarks, and offered the sum of £50 if started within six months. Other sums of money were promised from various parts of the country, but still there was nothing done. As usual, the correspondence bristled with suggestions as to what others must do, but every one was too busy to take the initiative, and again the matter dropped.

In the spring of 1878 the matter was again broached, and, entirely upon his own responsibility (and without any plan cut and dried), the present secretary called a meeting at his house in Brixton, which was attended by about thirty assistants. Money was subscribed for preliminary expenses, and a Provisional Committee formed, to consider the form the Association should take, and to call a large meeting at some place in London. An aggregate meeting was held at the Arundel Hall, which was largely attended. The Provisional Committee submitted two schemes for consideration, one based upon the Forest of Dean, and the other the form now adopted. After an animated discussion, the constitution we have the honour to represent was adopted. The Provisional Committee was enlarged, and power given to add to their number. Since that meeting, the Board of Management has been formed, and working harmoniously together, to establish the Photographers' Benevolent Association upon a secure basis.

The earlier meetings of the Board of Management were held at the residences of the various members; then Mr. Gansly (late deputy-chairman) gave the use of his sitting room at 174, Fleet Street, and the meetings were made to meet there regularly, at the rent of 6s. per night.

Hypocritics may be disposed to sneer at the expenditure in comparison to the receipts; but let it be borne in mind that the expenses would not have been larger if the income had reached its present annuities. The Board of Management, therefore, put it to itself great credit that the Association has been established for a sum of money that will bear comparison with the cost of establishing any such association.

To photographers and assistants the credit of the income belongs, and as the Association is now established, we have to be the pride of the profession to see that the income is always large. The pride of the Board of Management will be to keep down the expenses as regards the working; and there will be desire to meet all applications for relief in time of distress.

The Board of Management may by one application for relief, which, after due investigation, was awarded £5. Amongst other benefits accruing from membership, that of the Employment Register will, it is expected, ultimately be a very useful feature.

In conclusion, the Board of Management appeal to photographers to help them in their labours—employers, by sending donations, and using their influence in inducing their employes to join; assistants (male and female), are urged to join the Association, and help to make the Photographers' Benevolent Association thoroughly representative of the importance of the profession.

Signed on behalf of the Board of Management,

W. T. Wilkinson.

THE PHOTOGRAPHIC NEWS. (January 15, 1875.)

W. W.-As the squeeze only comes into contact with the back of the print in enamelling, we do not think there is serious danger of using vulcanized inebriated rubber for the purpose; but, as a matter of fact, the rubber is not necessary. It might be with a piece of pure india-rubber; or a piece of gutta-percha might answer. It would not be difficult to make a squeeze of pure india-rubber. This sheet india-rubber can be obtained, and cemented together, and give perfectly equal results in the making of india-rubber coats that are made by dissolving india-rubber in chloroform or in bichloride of carbon.

2. Nitrate of ammonia is more difficult than nitrate of silver and its presence in a printing bath would prevent the paper acquiring a homy dryness. The proper strength of a nitrate bath must depend on the salting of the paper. Most of the commercial samples of albumenized paper in the market are made with a view to enabling silver bath to be added. The addition to the nitrate bath would be necessary, which we have never made. Most stationers will be able to supply, or procure for you, Whatman's dry gum paper. For the dirty or weakly coated, Soho Square, will supply it. If you look carefully you will see that one and a half grain of the quantity of bromide of ammonium is to be dissolved in a drachm of alcohol and added in the ounce of ordnance of bromide of gold. This will completely dissolve the quantity in less alcohol, but if you dissolve it in less you may do so.

H. VORLST.-Until you have been accustomed to the practice, it is not convenient to use an eye-piece for focusing. In our own case we much prefer to focus by the unaided eye, and we find no difficulty in getting perfect sharpness. There is nothing made to secure the right focus of the eye-piece except screwing it out or in to suit your eye.

II. S.-You do not state what kind of direct copies you refer to. As a rule, the triple is a capital copying lens. A portrait lens well stopped also answers well.

R. G. M.-We cannot with propriety express an opinion on the subject.

2. The Osmometer eudichloride paper has, in our hands, great brilliancy.

C. M. F.-Cautiously allowing the plate to remain in the bath long enough to increase the sensitiveness of the plate, the risk of fog will be reduced. The presence of iodide and bromide, not converted into salts of silver, will tend to keep the shadow clear, but will also multiform the photographic image. This is a subject, which, in relation to wet plates especially, has received too little attention.

J. C. W.-Formic acid does not work as a restorer; it is still weaker than nitric acid. It will not increase the sensitiveness of the plate, and is subject to the risk of fog. The presence of iodide and bromide, not converted into salts of silver, will tend to keep the shadow clear, but will also multiform the photographic image. This is a subject which, in relation to wet plates especially, has received too little attention.

D. L.-There are two or three ways of obtaining comparatively soft prints from hard negatives. One plan consists in slightly runing the paper before placing it under the negative. This, whilst it does not of course give a perfect gradation, by removing the hardness of the contrast gives a certain faintness which is often needed. Another plan consists in removing the fixed silver from the paper, as soon as it is sensitized, by the use of clean blotting-paper. This will materially reduce the contrast in the print, and allow detail to be brought out in the dimmer lights, without burying all the detail in the shadows.
PHOTOGRAPHY IN AND OUT OF THE STUDIO.

ENGINEERING PROBLEMS SOLVED BY THE AID OF PHOTOGRAPHY—PHOTOGRAPHY IN PERIODICAL LITERATURE—
THE KING OF SIAM'S INVITATION—PRINTING ON FABRICS.

ENGINEERING PROBLEMS SOLVED BY PHOTOGRAPHY.—There is one useful application of photography to which little attention has been called, notwithstanding the important employment that has been made of the art in this specific direction. It is the aid it gives to engineers and constructors to which it can assist the intelligent and assiduous, who would not have known how well and thoroughly by any other means. Two instances have recently come under our notice which will demonstrate how greatly the camera may assist in the carrying out of great works of an engineering character. In India, recently, at one of the cities in the interior, it became necessary to transport a solid block of metal, weighing something like a hundred tons, from one part of the town to another, and the question how best to do it very naturally arose. One could scarcely construct a carriage for it, neither would it have been an easy matter to place such an enormous mass upon a vehicle of any description. Advice was sought for in England; and as the movement of enormous masses by our engineers at home is not of uncommon occurrence, the authorities in this country, at the first opportunity they had, conducted a series of photographs to be taken, showing the removal of a large mass of iron from the foundry. One picture showed the manner in which first one side, and then the other, of the enormous casting was raised, and a platform placed beneath; a second photograph demonstrated how two bars of iron, turned up at each end, had been put beneath to form a sort of fulcrum, and another further demonstrated how rollers were afterwards thrust under this sledge, and the big structure thus moved slowly and surely along. The advantage of such a series of photographs as this, with the men all at their stations, furnished with crowbars, jacks, and other necessaries, must be obvious to all; and those knowing something of practical engineering could not fail, like a layman experienced in part of the town, seeing how the most minute and trivial variations, in peculiar difficulty, and the rigging up of crabs and capstans, arrangement of the rope and tackle, necessitate some considerable experience on the part of the engineer. This being so, it has been decided, in the case of an iron pier which is now being constructed in London, to take a set of large photographs as the work progresses, showing the whole manner of working from first to last, so that in future, by a kind, a fortunate manager provided with copies of the pictures may not meet with any difficulty in undertaking the work, nor lose time in trying one system or the other, before settling upon a trustworthy plan. It is in fulfilling functions of this kind that photography will be invaluable to the engineer, and in the course of any future undertakings of importance we may rest assured that every step of the structure towards completion will be accurately delineated.

Were we in possession, for instance, of photographs showing the Menai Bridge in course of construction, or other similar great works, such would be not only exceedingly useful for the instruction of youthful engineers and pupils, but they would be, moreover, most valuable aids in the completion of other works of a similar nature.

PHOTOGRAPHY IN PERIODICAL LITERATURE.—A little while ago we called attention to the use made in America, and more recently by the New York Daily Graphic, of photography in reproducing MSS. and sketches, and dwelt upon the fact that although much has been done in this country to work out photo-mechanical processes, very little advantage had been taken of these in Great Britain by our periodicals. A great change has now taken place during the brief interval that has transpired, and, instead of having but one journal—the Figaro programme—which photography aids in illustrating, we have three weekly papers now appearing regularly with photo-relief prints, and one in which a kind of photo-lithography is largely employed—a comic journal called Funny Folks. In the latter case a very perfect process appears to be used, judging by the results we have seen, for the foreign cuts and lithographs reproduced might very well be considered with those formed by a photo-zinc-lithographic method, for we are told that after the image is taken it is first put upon zinc and afterwards on stone. Now that collotype printing is also steadily progressing, we may hope to see further ventures made by publishers, for as yet there is one great branch of the art untouched—the vulgarization of photographic views and landscapes. Some pictures we have seen of Rhine scenery produced by the last named process were so excellent as to lead us to the belief that in a very short space of time we shall have illustrated journals containing little else than landscapes produced from first to last by the photographer. But for these great applications of the art to industrial purposes, disciples of the camera need not despair, for, let pictures be drawn as you will on the screen of the camera, if you work at it, you will get your photographic after and well paid for. Neither the landscape photographer nor the portraitist need be under any apprehension of their work being cheapened by the multiplication of views and portraits that is becoming every day more extensive, for, however much the mechanical departments of the art may be simplified, chemical and artistic knowledge on the part of a photographer must always command a position.

THE KING OF SIAM'S INVITATION.—We are very glad to hear of the invitation sent to our scientific men by his Majesty the King of Siam to witness the approaching eclipse of the sun in his dominions. The invitation has been made so politely, and with such liberality, that if it has been extended to other European nations besides ourselves, there is a probability of the hospitality of his Majesty being severely taxed. Both the Royal and Astronomical Societies have been asked to send deputations to witness the phenomenon, and these two bodies have resolved to send some half-dozen gentlemen at least. The wording of the King's letter is especially gracious, for not only will it give him pleasure to erect one or more observatories in any portion of his dominions for the temporary use of his guests, but he further states that the whole staff that comes over will be treated as private friends of his own. It proves something for the Siamese nation that they have such a respect for the votaries of science.

PRINTING ON FABRICS.—In the 1873 exhibition of the Photographic Society, it will be remembered by many of our readers, there was a charming imitation of black lace upon a white parasol. A very fine and expensive bit of real lace had been photographed, and as the result was merely a black and white image, no difficulty was experienced in converting it into a mechanical printing block. In this case a gelatine film was employed, and either the Lichtdruck or Albertype process, so that the image was
preserved in all its delicacy, and every fibre of the lace shown with extreme sharpness. So perfect was the result, indeed, that, unless one touched the parasol, it was impossible to believe that the lace was not actually a tangible reality. The same process is now being further employed for printing upon handkerchiefs and shirts; and we were fortunate in seeing the other day some more examples of what can be done in this delicate fancy printing process. Some of the designs upon the three butterflies most charmingly impressed, the images having evidently been taken direct from the insects themselves. Other fabrics had sketches, evidently reproductions from woodcuts and engravings, obtained and printed by a photo-mechanical process, all of them being of a most delicate nature, such as could hardly be secured from blocks on lithographic stones. Photographic portraits of various kinds were also to be seen impressed upon fabrics in the same way; but these, perhaps, can scarcely be called novelties, neither was the result so successful as in the case of the other objects we have mentioned. The prints were undoubtedly all produced by fatty ink, and would, no doubt, be very permanently printed upon the fabric. This method is much simpler and more satisfactory than printing in the ordinary way by means of silver salts, for very great care has to be exercised in the latter case, and failures are far from unfrequent, the dressing in the fabric being most difficult to remove and apt to discolor the silver print. Moreover, there are the troublesome operations of salting and albumenizing, and flattening the stuff, which is by no means an easy proceeding any more than the elimination of the print in the pressure-frame. This photo-mechanical printing upon fabrics is certainly an art to be cultivated.

THE ORIGIN, AIM, AND ACHIEVEMENTS OF THE PHOTOGRAPHIC SOCIETY, WITH SUGGESTIONS AS TO ITS FUTURE DEVELOPMENT.

BY GEORGE HOOPER.*

The Photographic Society was founded on the 30th of January, 1853, the first meeting being held at the rooms of the Society of Arts, John Street, Adelphi. Its first President was Sir Charles Eastlake, P.R.A., and it had Earl Somers, Sir W. J. Newton, and Prof. C. Wheatstone as Vice-Presidents. The President of the Council were Dr. Hugh Diamond, P. le Neve Foster, M.A., Robert Hunt, F.R.S., Dr. John Perce, George Shaw, and Captain Scott, R.N. Alfred Roslyn acted as Treasurer, and Roger Fenton as Hon. Secretary.

In this paper I shall review some of its special achievements, both in encouraging art and scientific research; and after taking this retrospective glance, make suggestions of a practical nature as to the best means to be adopted to increase its usefulness, and thereby raise the status of the art generally, and necessarily those who practice the same, in the eyes of the public.

The art of photography will doubtless be handed down to all ages as one of the most important inventions of the nineteenth century.

It not only has been the means of creating a new industry, but has itself become more or less connected with every other known industry, so that whether it be religion, law, politics, manufacture, or education, it plays its part. It has, like the telegraph, brought all the world together, so that we can familiarize ourselves with the features of every race of mankind and study their habits and customs.

In fact, to summarize its immense capabilities, we may say that things animate and inanimate have been represented with a truthfulness otherwise unattainable, and even things so minute as to be invisible to the natural eye can be easily photographed and enlarged to prodigious dimensions.

Science generally has benefited by photography; a love for real art has been generated, as well as a deep regard for that which is both truthful and beautiful. This can be proved by referring to many of the topics that have been so ably brought forward and discussed at the meetings of the Photographic Society. Daguerre, Fox Talbot, and Archer are three of the names that will always be inseparably connected with this fascinating art.

The Photographic Society, which began its career under the most flattering and encouraging circumstances. It had Royal patronage; many of the nobility figured in its rank; funds were lavishly expended, and within four years it had over one thousand pounds in funded property.

It is generally considered every thing to start well; but we have also heard it said by wise men, "That early success, unless accompanied by experience, often leads to a rapid decline," and this was somewhat the case with this Society. It began too well, considering all experience had to be gained; and this experience almost cost the Society its life. However, thanks to the determined energy of some of its most constant and earnest friends, and this sudden and rapid decline, has for years been on a firm basis, and may now be said to have a good constitution.

The Photographic Society has arrived at its majority, and is this very month entering upon its twenty-second year; nevertheless, it cannot be said to be full-grown. Far from it; for there is yet an immense field of usefulness ahead, and the Photographic Society of Great Britain will take it. This is this sudden and rapid decline, has for years been on a firm basis, and may now be said to have a good constitution.

Far from it; for there is yet an immense field of usefulness ahead, and the Photographic Society of Great Britain will take it. This is this sudden and rapid decline, has for years been on a firm basis, and may now be said to have a good constitution.

A brief review of the past proves how productive the young art was when this Society commenced in 1853.

Four papers were read at the very first meeting, one being "Photography in an Artistic View, and as a Branch of the Art," by Sir William J. Newton; another on the "Wax Paper Process," by J. Percy, M.D.; another entitled "Photography as an Aid to Engineers," by Sir C. Vignoles, C.E.; and the last, a paper "On the Mode it is Advisable the Society should Conduct its Labours," by Roger Fenton, Hon. Sec. At the second meeting "The Lenticular Process" was the principal discussion; at the third and fourth meetings, technical matters amongst the Society's members were discussed. Sir Charles Eastlake, the President, was able to announce that Her Majesty the Queen and H.R.H. Prince Consort had consented to become the Patrons of the Society.

Next came papers by Mr. Claudet on the "Daguerreotype Process;" by Dr. Diamond on the "Calotype Process;" and Roger Fenton on the "Nitrate Bath," also by Mr. Wenham and George Shadbolt on "The Production of Large Prints from Small Negatives." It was at this period that John Spiller (our President) first published a formula for preparing a "Protonitrate of Iron Developer."

The Society's first exhibition of photographs was opened on the 3rd of January, 1854,* with a soirée at the Suffolk Street Gallery, the Queen and the Prince Consort taking a private view at eleven A.M. of that day. This exhibition remained open two months. We would mention here that the Journal of the Society was at this time very popular, having as its contributors many gentlemen of scientific eminence; it was sold at threepence per number to non-subscribers, and had (we believe) a circulation of between three and four thousand copies.

January, 1855, the Exhibition was held in the Gallery in Pall Mall East. The following month, Sir Charles Eastlake retired from the Presidency, and the late Lord Chief Baron (Sir Frederick Pollock) was elected to the position. In the same year a committee of seven gentle-

* The first exhibition of the Photographic Society was held in the rooms of the Society of Arts at the latter end of 1853.—Ed.
men was formed to investigate "The causes of fading of positive prints." The Society voted £25 towards defraying the expenses, and the Prince Consort gave £50 for this same object. Mr. J. E. Mayall read a paper on the "Dry Colloidion Process," and in September the Tauenepot process was introduced, January the 3rd, 1856, the Society appointed a paid Secretary and Editor at a salary of £300 per annum; prior to this an Editor received £100 per annum; an assistant editor, £200, the sale of the journal realizing the Society about £100 per annum.

In February, 1857, the Society had £1,650 in hand; but the expense of changing its premises decreased this amount to the extent of £700 by December. Within two years of this time the entire funds were eaten up, and an expenditure in excess of income to the extent of £636 16s. 7d. had been made.

In May, 1857, an event worth chronicling occurred, as a proof of the good feeling that existed in the profession at this period. It was on the occasion of the death of Scott Archer, whose wife and family were left unprovided for, when the Society, led by Mr. Mayall, started a subscription which ultimately realized £247, and Sir Wm. J. Newton, addressing an earnest appeal to the late Earl Derby for a pension for the three orphans, obtained for them an annuity of £50. At the Exhibition of 1859, carbon prints were shown as a novelty, and alkaline gold toning referred to. In the same year a Colloidion Committee was appointed, and issued a report.

During the session of 1860-61, the Society lost its patron, the Prince Consort; but no other event of importance occurred. From the Report of the Society for this year, I extract the following sentence:

"To the Royal Society there is yearly appointed a Government grant of money to be expended in furthering scientific investigation for the benefit of the country. The Council of the Photographic Society, pointing only to the practical results heretofore attained under unfavourable circumstances, would venture to suggest that assistance should be granted by Government towards improvements in the processes of photography. It would serve to determine many difficulties, and tend to increase advantages now derived from the various employments of art in the different departments of the Government. A yearly grant, if the money were to be substituted for or in addition to the present supply, and reserved for the purpose of procuring a supply of the materials which are used in the art, would be of great assistance towards the advancement of the art, and assuredly more than repay the expenditure."

In 1864 the carbon process of Mr. Swan was first introduced. The introduction of this process, that has since grown to such dimensions, was the occasion of a very large attendance and an animated discussion.

It is remarkable that in the address at the annual meeting of the Society for 1865, the Lord Chief Baron said, "He entertained the same zeal for the progress of photography, whether as an art or a science, as he had ever done. Although he was not so young now, nor so able, perhaps, actively to illustrate that zeal, still he was capable of rendering them some service, and he hoped to save them some expense in a place for meeting." Then came these significant words, which I am particularly anxious to draw attention to: "It was notorious that other societies with no higher claims to the assistance of Government, were provided with rooms at Burlington House. Almost every society with any claim whatever had rooms there. He purposed going there himself next day to ascertain how far, in point of fact, accommodation could be secured for this Society; and if he found a suitable room to be had, he would make application to the members of Government with whom the matter rested, and obtain sanction for this Society to be accommodated." In the same year Mr. Simpson introduced the useful and beautiful collodio-chloride process, and Mr. Woodbury the photo-relief printing process.

It was at the Exhibition of 1867 that the twelve photographs lent by the great French artist, photographer, and sculptor (M. Adam-Salomon) brought about what might be truly called a revolution in English portraiture.

The session 1865-69 was an important one. Sir Frederick Pollock retired on account of his age, being then in his 86th year, and James Glaisyer, F.R.S., became President of the Society. At the annual meeting in February 1868 he made a spirited address to the members, urging them to use every effort to put the Society in a good position financially, and had the gratification of seeing this effected within a short period. I quote a sentence from the address of the President on this occasion, as it shows the important part played by photography in its immediate connection with science:— "Who could feel the value of photography more than himself? But for photography he or his assistants would frequently be workers and watchers all night long. The records of the registration of their instruments required taking once in every two hours; and little rest was obtained under such circumstances. They had to record the variations in movements so delicate that the finest spider's web was sufficient to arrest the motion." It could only be registered by an imponderable, and that imponderable, was "Light," and the process "Photography." He could speak with much feeling and appreciation of what photography had done for science and for the future of science. They knew too that photography had a great future, and he hoped that each member would resolve to take his share in it.

At the next meeting of the Society another very interesting demonstration of the photo-relief printing process was given by Mr. Woodbury. I shall pass over the review of the last four years, considering its history as fresh in the memory of us all, and put it to you to say that the Society has steadily progressed, its annual exhibitions have become increasingly popular, and its financial position good.

Having, then, taken this retrospect of the work of the Photographic Society, and traced its history, and necessarily, to a great extent, the history of the progress of the art to the present time, let us now consider the best means that can be adopted for the future of the art, and the way we love, and the part to be taken therein by "The Photographic Society of Great Britain." To rest upon our laurels, or, with Earl Russell, "Rest and be thankful," cannot be the motto of a Society that represents so productive an art as ours; and until many things that now appear almost impossible not only become possible but practicable, we cannot afford to entertain such thoughts; and this is that has tempted his to make certain suggestions the practicability of which, I trust, will be thoroughly discussed at this or some future meeting, and action taken thereon. For the sake of being explicit I shall divide my subject into three heads:—

1. The necessity of obtaining as soon as possible a Royal Charter, and thus possess the power of granting diplomas for merit.
2. Our claim upon the Government for a money grant, and suitable premises wherein to hold our meetings, exhibitions, and have permanent offices.
3. The necessity of forming committees for scientific investigation that shall annually report their results to the Society.

First, then, let us discuss "The necessity of obtaining as soon as possible a Royal Charter, and thus possess the power of granting diplomas for merit."

An attempt was made to obtain a Royal Charter some years since, but it proved unsuccessful from causes easy of explanation; this, however, is not likely to be the case.

* This allusion is made in error. Mons. Adam-Salomon did not send or exhibit his works; the examples of his work exhibited were some in the possession of Mr. Wharton, who lent them to this Exhibition.
THE FADING OF SILVER PRINTS.

We publish on another page an interesting letter on a question of vital importance to photographers, written by a gentleman whose skill and experience in the art give unusual weight to his observations. Captain Ross's name is associated with some of the finest pictures which have graced the walls of the photographic exhibitions, and his experience over a period of twenty years, given in the course of that experience he has produced prints which have faded, and prints which remained permanent for upwards of twenty years; a result probably common to the labours of all old photographers. But the point of especial interest consists in the fact that he has carefully noted the causes in operation in both cases. His experience teaches no new doctrine; its value consists in the weight it gives to lessons before taught, but unfortunately too often forgotten or overlooked, namely, the vital importance which attaches to modes of washing prints to remove all traces of the fixed salt, which, if unrecovered, are fatal to the stability of the print. The common mistake is to suppose that long soaking constitutes thorough washing. With every supposed appliance for thorough washing, Captain Ross has found what so many have found, that some prints faded; but he has also found that this fading was due to the failure of the appliances to effect the desired end, owing to prints sticking together in a mass, and so preventing each one from being subjected to the action of a constant change of water. We have often insisted on the importance of rapid washing in many changes of water. Where this is done, and the prints can be washed a few at a time, there is little risk, if the fixing process itself has been properly performed, of the prints fading. Where the prints in hand are few there is not much difficulty in draining each carefully and thoroughly between the rapid changes; but in establishments where the number of prints daily produced is large, this is more difficult. In such cases, washing for thorough soaking to the foot of the running water is desirable. We have urged before, and we repeat the advice, because of its importance, that two or three times during the process of washing the prints should be placed in an even heap and subjected to heavy pressure, to remove as nearly as possibly every drop of moisture. The prints should then be separated and singly placed again in clean water. Such a process two or three times repeated for thorough soaking by Alex Alexander will more effectually wash a batch of prints in an hour or two than many hours soaking in water without attention to their separation, so that the whole surface of every print may be subjected to the action of fresh water untainted by the traces of hypo-sulphite. We strongly commend the various suggestions of Captain Ross to the attention of our readers.

OBITUARY.—O. G. REJLANDER.

A great man has passed from amongst us. We have to announce with profound regret the death of the father of art photography, Mr. O. G. Rejlander, in the sixty-second year of his age. A lingering illness of many months standing terminated on Monday morning last, when he calmly fell asleep.

Of the early life of Mr. Rejlander, we have but brief resources to derive from occasional remarks in conversation. By birth a Swede, he lost his father, who was an officer in the Swedish army, early in life, and began his struggles very young. With an earnest passion for art, he early devoted himself to painting, and maintained himself whilst studying in Italy, by copying the great masters. Subsequently he came to England to devote himself to his profession as a painter, and whilst so engaged he came under the glamour of the new and marvellous art of sun-painting. He felt its rare and subtle power with an artist's instinct, and the inherent limitations of that power, and the further limitations imposed by imperfect appliances, only stimulated him to varied ingenious effort to supply the shortcomings these limitations involved.

The well of Mr. Rejlander would not only be full of interest and instruction; but it would necessarily furnish most important contribution to the history of the art development of photography. Amongst the first, the ablest, and most persistent of exponents of the pictorial capacity of the new art, a quarter of a century of his life has been devoted to a practical demonstration of its claims. Chance or choice fixed his residence for many years in a district perhaps unsuspected for facility or suggestion in connection with art photography. In the town of Wolverhampton all his early works were produced. The "Two Ways of Life," the first photograph of ambitious aim in pictorial composition, although by no means the first photograph with pictorial aims produced by Mr. Rejlander, as well as others was produced here from the poor cells of a cotton factory, a genuine specimen of a "black country" town. The especial object of this picture was to illustrate art capacity in photography for the Exhibition of Art Treasures at Manchester. Many photographers will remember the varied criticism which this picture evolved from both artists and photographers, criticism which as Mr. Rejlander once confessed to us, consisted more than half to his own disappointment than of real appreciation. The history of its production and the result are full of interest, and although twenty years have elapsed, and the art of combination printing has progressed greatly, the work remains a marvel of photographic skill and art excellence. In his early photographic labours, especially, the difficulties attendant upon photographic pictorial effects seemed to possess an absolute charm. The delineation of a subject like the "Head of John the Baptist on a Charger" would seem at first sight to be quite beyond the legitimate range of photography; and in later days Mr. Rejlander himself confessed that it was so; but in the enthusiasm of his first love, he believed the art of his adoption might effect anything. The picture in question was an undoubted success. A nobly modelled head, the heavy locks of hair, damp with the dews of death, resting on a charger, the ghastly effect of excision covered with a napkin. For two years, Mr. Rejlander once told us, he saw that head on a body walking about the streets at Wolverhampton; he never saw it without a yearning to place it in a dish as we saw it in the photograph, and he never rested until he made the acquaintance with its owner and obtained his permission to take it off. Higher and more wholesome in aim and character have been the many thousand of simpler pictures and studies which have teemed from his camera. The especial quality of his work, the most trivial as well as the most ambitious, was the presence at all times of a thought, an intention, a definite idea, in every picture. He believed in the capacity of photography. "If I cannot see," he said, very early
EXTRACTS FROM A LETTER TO A YOUNG PHOTOGRAPHER.

By Alexander S. Mackay.*

There is another matter concerning the management of portraiture that I shall take the liberty of referring to: I mean not reflected lights, which are generally so many degrees below the principal or daylight of the picture, but all-sided lights, which not only destroy all roundness, but invariably produce the most grotesque squints. In small cartes this was past muster with those who are not painters, but enlargements to the size of the above and you will at once find what a miserable result you have. If at all possible, let your light always flow from one direction; I press this upon you as of much importance.

Let me say here that a most reprehensible practice in your art is that of touching negatives—I mean beyond the removal of mere specks. A portrait can only be acceptable if it represents the character of the sitter in the faithful rendering of his facial development; and to fritter this away, with the avowed purpose of softening or beautifying the head, is the most absurd of all absurdities. I don’t think the public are at all enamored for touched cartes; it seems to me an itching some have to make their work pretty; yes, alas! merely pretty; they don’t consider the sacrifice they make. If photographs were taken under a well-disposed light, with the character of the back-ground, there would be no necessity found for touching; There is no reason why negatives should be very complete, and when they are not so, it must arise from the absence of a preconceived mental arrangement of the subject. Thus “Evil is wrought by want of thought, just as well as want of heart.”

I sincerely hope that henceforth we shall have as little touching as possible; we should have none of it, especially in the portraits of distinguished men: the great men whose memories the people cherish and revere, they wish to see them as they appeared in the flesh. Amongst the celebrated divines, for example, we have in their portraits Drs. Chalmers, Blackham, andCandlish, all wonderfully characterful heads; another great name has just occurred to me, that of Hugh Miller; and I would ask, who would have dared to polish down his rugged front? To tamper with such heads would be giving the lie to our successors—it would be depriving posterity of its hereditary rights.

I desire now to direct your attention to what are called “Rembrandt portraits;” this, I am afraid, is rather a comical misnomer, in as far as they bear any resemblance to the portraits of Rembrandt; I should like to know the point of contact, or the principles on which they have been thus christened. The luminous transparency of that great master’s works has been, and will continue to be, the admiration of every succeeding age; in many of his pictures there are not above ten or fifteen per cent. of positive light, but the remainder is by no means blackness, but a glowing darkness, in which the details are almost as well made out as in the more prominent parts. I had sent me recently, for enlargement, heads of a lady and gentleman in this particular manner; the heads were totally in shadow, excepting that down the off or narrow side of each there was a clear, sharp outline of light, which, in the gentleman, also struck the outline of a well-pronounced aquiline nose; both heads reminded me forcibly of the moon nine-tenths in eclipse, and had they been enlarged their appearance would have made both day and night hideous. Of course they were declined, and ordinary cartes substitute with marked advantage.

In the above remarks, I think you cannot fail to see my drift. I have been very frank in pointing out to you the means by which you may purify your art, and I have given my opinion on the several matters alluded to, and, on consideration, you will just take it for what it is worth. I am very anxious that you should leave no stone unturned by which you may acquire a thorough knowledge of your business; you should lose no opportunity of becoming familiar with works of established reputation, either in early or more recent editions. What is the use of having art depositories if art is not numerous, and, after all, little else but a numb show to the uninitiated; the sight of several good pictures will appeal more eloquently to your feelings, than many volumes merely theoretical, could possibly do.

With regard to objects of photographic study, I may say a few words. With the exception of works purely historical, or those compositions that appeal more immediately to the imagination, there is little to be gained from our province. I am, however, on the point of stating the fact has already been amply proven. Although in the mass of subject matter at your command, there will always be a difference in degrees of excellence. Scotland is peculiarly rich in magnificent scenery. Amongst those monuments of creation, the everlasting hills, you may feast to your heart’s content; in fact, the whole of the “land of mountain and flood” you may figure as a grand novel which a modern enthusiast -one more finely calls “frozen music,” there is superabundance of material. Our old castles are a never failing source of interest, and those of our own country would form rather an imposing album. Let us not forget our old baronial trees, our druidical oaks especially, with their fine anuity of branchification. What useful auxiliaries to the landscape painter were our ancient beech trees! I do not mean for servile copying or adaptation of any kind, but simply for their very suggestive-ness. I have in my possession an excellent photograph of an old ash, uprooted by the severe storm of two months ago, on the estate of Robert Dundas Esq., Arniaston; this tree had obtained a somewhat patriarchal age, being no less than four centuries old. In its prime it forms a very agreeable feature, however; it stands out against immense beach, the height of which forms the principal point in the composition. This is a work by our treasurer, Mr. Pringle.

It seems to me there can be nothing more worthy of attention than magnificent ruins; the excavated remains of cities thickly peopled in times long past, they strangely kindle our emotions, probably from the fact that we associate those objects with this human feeling. To contemplate them without irrepressible awe is simply impossible. “Our fathers, where are they?” must rise to every human lip. I think also of the simple photographic tone is the best medium by which such objects can be expressed, as if being starved even of a glow of colour, adds more intensely to the feeling of the utter desolation. The feeling I would most express has been frequently shown in the Queen Street Hall, and at the very last meeting we had a most brilliant display, by the oxyhydrogen light, of “Egypt and the Nile,” in t.e exhibitions of her ruined temples we had many glimpses.

“Through the dark postern of time long slumbered.”

I would now only remark to you, that you are absolutely and uncompromisingly to pursue your taste, and anything that bears not that sovereign stamp in all the human intelligences, will inevitably perish; truth, that small but significant word, is all powerful. The vast systems revolving all around us in the heavens are regulated in obedience to its spirit, as it is one of the principal attributes pertaining to the Deity, for he is Truth as well as Love.—Yours, &c.,

Alexander S. Mackay.
in their studios, than would be the case if the pictures were hanging on the walls of an exhibition. The maximum time allows 1 to each member is four days; and as each portfolio contains about a hundred prints, the time allowed is none too much.

The institution of wonder albums in England would, we think, be of benefit to many of our brethren in the country.

Critical Notices.

REPERTORIUM DER PRAKTISCHEN PHOTOGRAPHIC. Von FRITZ HAUGK.—(Weimar, 1875. B. F. VOIGT.)

We are glad to receive so practical a hand-book as the one sent us by M. Haugk. It contains a godly mass of information, and, what is better still, the facts are well tabulated and easy to find. M. Haugk tells us his work is suitable for the beginner, the amateur, and the professional photographer; and although the latter, if they have attentively read the photographic journals of late, will find little of novelty in the work, it will be, at any rate, a convenience to have the improvements of the last few years bound up together in a volume, to be referred to at any moment.

Many manipulative instructions have been left out as being considered unnecessary and we agree with the author in saying that those who desire initiative into the art of photography should seek instruction in the first place under a master, who will teach them in a few hours what they could never learn from a book in the matter of handling plates, dipping, working the camera, and other practical manipulations, which must be seen to be thoroughly understood.

In describing the printing processes, M. Haugk goes very fully into the matter of silver printing, and gives many important hints about mounting, pressing, and finishing, which professional photographers will thank him for. He also touches upon the collodio-chloride process, and the necessary directions for printing by means of that method; but, singularly enough, there is no mention of printing in pigments, which is now practiced successfully in many studios; nor of the Lichtenbruck or Albertype processes, which just now bid fair to be taken up extensively by portrait photographers. The beautiful specimens of portraiture that have recently been produced in Germany and England by mechanical printing makes us particularly interested in the branch of the art at the present moment, and we should have been thankful for particulars of the most improved Lichtdruck process as now practised.

As a laboratory companion for all ordinary purposes M. Haugk's volume, however, appears to us admirably suited, and we shall have pleasure in placing before our readers a few interesting extracts from it. The author has not forgotten to make mention of the failures that arise in practising photography, nor the cause of their origin; indeed, so much is said about them that beginners who are not very ardent in their desire to learn, might feel tempted to turn back at the outset when confronted by such a legion of obstacles. We do not think much can be learned from books in the way of correcting defects; these can only be combated successfully by experience. Indeed, a good photographer, like a good general, is only to be tested by misfortune.

One of the most useful portions of Haugk's treatise is the collection of tables at the end, in which the equivalent of millimetre and centimetre and grammes, and other French decimal measurements and weights, are given. It has now become a European custom to adopt the gramme and metre; and scientific men in this country, who publish their experiences in English journals alone, almost invariably turn their numbers into the French equivalents, as being far more accurate and reliable. Photographers must, therefore, of necessity, make themselves acquainted with these measurements; and, when once learnt, they will be found more intelligible than our ounce, or fluid ounce, the value of which is always doubtful. We are glad to see one scale being gradually adopted in England, Germany, and France, and as weights and graduated glasses, marked with fractions of the grammes, and centimetre, are now to be purchased everywhere, the sooner we adopt altogether the metrical system for scientific work the better.

TINY TRAVELS. By J. AINSBY-STERRY. (London: Tinsley Brothers.)

We must confess that we feel some degree of compunction in introducing photographic readers to Mr. Ainsby-Sterry's Tiny Travels. These travels are so full of delicious laziness, such insouciant abandon, such disregard of every consideration in life, except bright, easy, unfettered enjoyment, and present such a contrast to the majority of the travels undertaken by photographers, who are generally terribly in earnest in taking their pleasures, that we really feel there is some danger of demoralizing our readers, in bringing them en rapport with such a book, and such an author. The tiniest equipment of the photographic rambler, the merest pocket camera, walking stick tripod, and sandwich-case-like box of dry plates, cannot be assumed by any one unaccustomed to the meaning but the tiniest impediments may be utterly unimportant, but the amount of pre-occupation they involve! The anxiety to secure that delightfully sylvan nook, when the wind will keep the foliage in a constant tremor; the still greater anxiety as to how the plates will develop when some especially charming bit has been obtained under the best conditions; the inevitable presence of purpose in every phase of the holiday each and all most delightful to the enthusiast, but all sternly forbidding the photographer to enjoy the dear delights of laziness so charmingly and subtly suggested in these Tiny Travels. Mr. Sterry in his travels never goes sternly to any purpose; he declines to have a purpose. He does not travel as the crown flies; but as the butterfly flutters. But he is the most delightful of traveling companions, always gay, always gay, never a novel. He enjoins all that he sees with quaint fancies and odd reflected lights which invest it with new interest. His humour ripples and sparkles like a streamlet in sunlight; and, in spite of himself, and almost unconsciously to the reader, he conveys much odd pleasant information. We have not attempted to describe the book, we might as well try to analyze a perfume, but we simply conclude with commend- ing it as a most pleasant companion for many a spare half-hour, affording in its reading a sense at once of refreshment and rest. And—if we must be practical—let us add that it contains a delightful chapter on Faded Photographs!

If "Tiny Travels" are replete with graceful fancies, Mr. Wilson's "Lantern Journeys" constitute a perfect encyclopedia of facts in relation to travel. The idea is an admirable one. Several hundreds of the scenes of interest and beauty which the camera has produced for the lantern and stereoscope, on the Continent and in the East, in America and England, are here briefly and graphically described, just such vivid and salient facts being given as are most likely to fix the individuality of the scenes on the mind. To every lover of the stereoscope, and to all in the habit of interesting young folks by lantern displays, this will form a welcome volume.

Mr. W. H. Franks, in an article, full of interesting matter, giving an admirable epitome of the practice of the best men connected with photography in the United States. We commend it as full of interest to English photographers.

THE TRANSIT OF VENUS.

A recent article in the Daily News, understood to be by a distinguished astronomer, has some interesting remarks in referring to the photographic success of Lord Lindsay's expedition to the Mauritius, and the special advantages of the photography of pictures by Lord Lindsay. These pictures are rude, but are necessarily so; the image which requires no subsequent enlargement. The writer says:

First of all, Lord Lindsay's party has secured more than two hundred photographs (one hundred and ten of them excellent) showing Venus at various points of her path across the face of the sun; and these photographs have not been taken by means of photo-heliographs, like those with which our De la Rue and the American, Rutherford, have obtained their beautiful sun-pictures. All the other details have usually employed the instrument, but astronomically unreliable, instrument. (We deliberately say unreliable here, not untrustworthy, which would express rather more than we desire to imply.) Yet it has been successfully demonstrated (according to Dr. Jeany's estimate of the probable error resulting from the use of photo-heliographic sun-pictures) that the measurement of the sun's disc would probably be greater than that which existed before the late transit. The method used by Lord Lindsay and the American astronomers is, on the contrary, almost perfect, theoretically.

Let the difference, which does not seem to be commonly understood (for many erroneous statements have been made on the subject), be here briefly indicated. Suppose we have a picture of the sun, with Venus upon its face, taken by the photo-heliograph, and another picture of about the same size, taken by the method of the solar image formed at the focus of the object-glass; and in the absence of any sufficiently exact means of determining the amount of this enlargement, we must trust to the picture itself to indicate its own scale. There, in the picture, is the sun with the disc of Venus upon it, and the distance of Venus from the centre of the sun bears a measurable ratio to the sun's diameter in the picture. It might seem, then, that we know all that we want to know. But does the sun's diameter in the picture correspond to the reality? Many of the collodion photographers have doubts, and if we are at all sure that this has not happened, may not the apparent size of the sun have been enlarged slightly by what is called photographic irradiation? Unfortunately we have every reason for doubt upon this point. In fact, the admission is generally made by Sir G. Airy, that a Daguerreotype is infinitely more perfect in this respect than a photograph taken by the method which he has, nevertheless, often employed, and he has been no harsher in his criticism of that method than is unreliable, and that the results obtained by it are untrustworthy. Now take the photograph by the other method. In this a perfect piano mirror, carefully tested, is so moved by machinery as always to send the sun's rays in the same horizontal direction towards an object-glass having a focal length of forty feet. (The mirror acts thus as a heliostat—hence the name we have given to the method.) This length is sufficient to give a focal image of the sun requiring no enlargement (in fact, the image is about four and a quarter inches in diameter), and the astronomer is not concerned to know whether the actual photographic image is correct. It is only necessary to estimate and correct out the last steps of the process by which the image is produced. He knows the exact focal length of his object-glass, and the size of the image is hence calculable at once, being precisely the size of a circle which, viewed from that distance of nearly forty feet, would appear as large as the sun. But, indeed, as will presently appear, he is independent even of this determination.

Again, the negative disc representing in the negative the black disc of Venus may have its outline blurred by irradiation; but whether much blurred or little blurred, it is equally blurred all round, and the position of the centre can therefore be exactly determined. Similarly the position of the object-glass itself in the field of the film; but he knows exactly how large it is without measuring from its outline, for he knows the exact focal length of his object-glass, and the size of the image is therefore calculable at once, being precisely the size of a circle which, viewed from that distance of nearly forty feet, would appear as large as the sun. But, indeed, as will presently appear, he is independent even of this determination. Again, the negative disc representing in the negative the black disc of Venus may have its outline blurred by irradiation; but whether much blurred or little blurred, it is equally blurred all round, and the position of the centre can therefore be exactly determined.

In the heliostat method he knows that an inch in his picture represents an inch seen at a distance of forty feet, or what is the same, the exactly determined focal length of his object-glass. In either case, therefore, the method is better than direct comparison with the image of the sun; and in the other they have to be compared with the image of the sun. The method of the heliostat is better than the former, and the astronomer should have been able to make some tests of the apparatus which he must have known were at least equal to that of Hobart Town, and nearly equal to that of the American station in New Zealand. Accordingly, we now have three excellent sets of southern hemisphere pictures obtained by the reliable method. The result confirms the axiom that these are equal to or better than those of Hobart Town, and nearly equal to those of the American station in New Zealand.

Correspondence.

THE FADING OF SILVER PRINTS.

Sir,—I am glad to find by the letters in the photographic papers that the attention of many leading photographers is again addressed to the all-important question of the fading of silver prints. I think all old photographers should give us the benefit of their experience by taking the steps they have taken to secure the permanence of their pictures, and the results. If they will take care of these prints, I am sure we shall gain much useful information.

Not wishing to preach what I am not prepared to practice, I shall tell what I have done; but before I do so, I may mention that I have been an amateur photographer as far back as I can remember. The only objection I have is that there is nothing like the print. But every year, for the last thirty years, have not only made my prints from 1854 or 1844, and have tried most of the processes that have since been brought out—Talbottypa, Calotype, wax paper, wet collodion, and dry plates. I have devoted much time and attention to this most fascinating pursuit, and it is no great exaggeration to say, that for the last thirty years very few days have passed without finding me occupied with some branch of photography. The result of my labours last me to take a much changing view of the permanence of silver prints than most photographers do. I believe that the fading of their prints is almost entirely due to some traces of hyposulphite of soda having been left in them.

It was, I think, in 1856 or 1857 that the Photographic Society of Scotland, of which I had the honour of being a member, but that they had taken to secure the permanence of their pictures, and the results. If they will take care of these prints, I am sure we shall gain much useful information.

Here, then, we have prints that have stood the test of twenty years, although I lately read a very delightful letter in your paper by one of our greatest London photographers, in which he said that few, if any, prints would be found that had lasted fifteen years. Mr. Tunny, a well known and most successful Edinburgh photographer, taught me the collodion process. He impressed on me the necessity of using the correct size of hypo, and how to prevent by various arrangements to do so ever since. In Edinburgh I had no convenience for washing prints; but I managed to do so by giving them from fifteen to twenty changes of hot water, and then a few washings in cold water. I placed them in a flat dish, not more than two or three at a time, and did not leave them in the hot water more than from one to two minutes, and I was always careful to drain off the last drop of water in the dishes. It is true, but may be leaving prints to soak for a length of time in the same water; it is the constant change of the water, and not length of washing, that removes the hypo.

I reside for the greater part of the year in the Highlands of Scotland, and for the last sixteen or seventeen years have adopted a very simple arrangement by which, without any trouble, I can thoroughly wash my prints. A had an
oblong box of block tin made, about two feet long and sixteen inches broad. At each end, and for the whole breadth of the box, there is perforated zinc. There are two trays, so that I can have three lots of prints at a time. I place the box in a stream, and allow the water to flow through it for four or five hours. Supposing the stream to run at the slow rate of a mile an hour, the print must have between eight and ten thousand changes of water in five hours.

Notwithstanding this thorough washing, I have had faded prints during the winter owing to having put too many in a tray; the stream rushing through the zinc netting crushed them in a mass against the end of the box, and in that way the prints inside the mass were not properly washed.

Photographers resident in towns cannot adopt this plan of working, but most of them can command a tap of water, and with a tub of block tin, a hole at the low side, a syphon, and a gutta-percha pipe communicating with the tap, they can wash their prints very well, provided they do not put too many in the washing tub at the same time.

I have mounted my prints in former years with flour paste, and latterly with starch, always having it fresh made. I see this mode of mounting pictures is pronounced to be certain destruction, but it has not proved so in my case.

I conclude this letter by saying that during the last twenty years I have printed many thousands of prints, and I have never had a failure, but these failures were due in a large part to my own carelessness in washing the hypo; when that operation has been thoroughly carried out, my prints have stood the test of many years.

Your obedient servant,

Horatio Ross.

1, Southwest Terrace, Southsea, 13th January.

METALLIC SPOTS IN PRINTING.

Dear Sir,—I see in your last week's issue an article on the subject of metallic spots in albumenised paper.

Your contributor seems unable to account for their presence, but, to my mind, the wonder is that there are so few. I am not acquainted with the details of the manufacture of photo. paper, but have been connected with that of ordinary book paper in this country for a number of years, and have very little doubt a similar process is carried out with a few extra precautions. M. Davanne says the particles can hardly be in the pulp, because the rags are so carefully overhanded, but he seems to forget that they are ground into pulp with steel knives. These not only collect scale and rust on their surfaces (which may, and will drop off), but the knives, especially the steel ones, magnetize the steel, and may throw off small particles of metal. The fact that the spots are found on the even side of the sheet, confirms me in the opinion, that they exist in the pulp, and are not communicated to the paper in any of the after processes. Anyone acquainted with paper-making knows that if there are any metallic spots, they will be on the under side of the sheet. This will be plain to anyone when they consider that the pulp is run on to the wire in a very fluid condition, the heavy particles, such as bits of metal, naturally sink to the bottom, and are therefore found on the under-side of the finished paper.

The only remedy I can think of, is to use the best steel for the knives. The common qualities being much more liable to chip, and to see that they are kept free from rust. If you think the above throws any light on the subject, it is quite at your service. —Yours truly,

A Paper Maker.

THE NITRATE OF SILVER BATH, AND HOW TO USE IT.

Sir,—The question of the use of the nitrate of silver bath, its evils, and its remedies, is again come to the front. A few words on the subject from one who has eighteen years experience with its use, under all circumstances and conditions, may not be out of place. Particularly as photographers are invited to purchase secret processes, that are alleged to cure all the evils incident to its capricious nature.

To assert that there is nothing in the "secret processes," would, in my opinion, be saying too much; our gentleman at least who offers it for sale, is a careful experimentalist, and has in another secret process produced work worthy of imitation. But how much there is new in the master is another question. If photographers would only exercise care and judgment in the management of the bath, there would be no need of purchasing ideas from other people. It is laid down as a matter of fact, that the larger the quantity of bath in use the less likely it is to do the work of order; this experience has borne out to be strictly correct for obvious reasons, which I will refer to directly. In my usual practice I do not use what is termed a large quantity of solution—from a quart to three pints is about the outside—but I can safely assert that I have never had to discard a bath from over-work, it has been from sheer accident whenever such a thing has taken place. My usual practice is, to make a bath of rain water, first putting a few grains of silver to precipitate any impurities. Then, with ordinary nitrate of silver, make a bath of thirty-five grains to the ounce. Sun again for a day or more, and filter, then coat a large plate, allow it to remain over-night, test for acidity. If not sufficiently acid, take pure nitric acid diluted and let a slight reaction be visible in the litmus, and your bath is in working order, and will continue to do so for almost a month or three days when you will have it in the finest condition. Now the grand secret is to keep it in this condition. This in my practice has been done, by simply replenishing with new plain forty-grain bath, and by simply keeping a cover of cloth over it to keep out dust, but that will allow the evaporation of ether and alcohol, the accumulation of which is the cause of some of the evils that are said to be heir to. It is too much in practice of photographers, during the busy time, to forget how quickly they impoverish the bath, abstracting the silver to a far greater extent than the liquid, and are only reminded of it, when poor and thin negatives that will not intensify make their appearance.

At this stage, replenishing the bath will make it, as a rule, all right. But things should not be driven to this extremity at all. After two or three days work the bath should be made up to its proper strength, and things will go on smoothly and pleasantly as before. In my practice, if these things are attended to, there will not be much to complain of pinholes occasioned by nitrates in the bath, or crystallization from the same cause through excess of ether and alcohol. It must not be over-looked, that the larger the quantity of bath the more rapid will be the evaporation of the alcohol, and must be compensated in the bath. But most commercial samples average about the same. Keep the bath up to an even temperature, winter and summer, and to an even strength, allowing facilities for the evaporation of ether and alcohol, and there will be no need to buy secret processes. There is nothing new in what I have said, but it may be worth something— I remain, sir, yours, &c. Thomas T. Bidford.

SECRET PROCESSES.

Sir,—I can only endorse similar sentiments to some of your correspondents. It is seldom I write now for either Journal or News. "Process selling" at the present day seems to have got a "rage" or "fashion." I can well remember the time when such would be ignored. True, many old "dodges" have taken new names: old processes sold as new, and rendered freely. The last one I purchased I was told was something quite new—"never before" published or used. When I got the secret, lo! I found it in print as soon as I got home.

For my own part, may I ask what are photographic societies for? I know full well I shall get, perhaps, a "warning." Pray readers excuse my bluntness. I am pure from the country, and cannot bosom of high flown language, but use my pen in my own fashion; and you must take the words that come from me in good part. Our
societies should be for advancement and improvement, and really to test processes the same as our scientific associations. Very true, we have clever men—men who devote much time experimenting, and expend money in going through the various formulas, &c., and I also maintain that these gentlemen should be repaid; but the question arises how, and by what means?

Professional men should by all means belong to some photographic society and contribute their share to such institutions, so that it would give the president and committee a chance; and in large towns where there is no society let them join the nearest, and give a helping hand to raise a fund for testing and proving vended processes. I saw a picture only the other day—a good one, true—and the background was put in powder colours, and shadows glazed; it put me in mind of days gone by glass pictures, when many times I wondered how these effects were produced, and by an amateur coach painter. This we called rubbing-in, and have used common carbon from the fire grate.

Many of my own county readers will remember, when Baume was in Leeds, powder colours were used by this gentleman’s artists (some Germans), and another establishment which paid quite a subscription for simple effects, were by far the best. We have now a similar method patented, and I have seen Mr. Stortz produce the same effect cleverly, only in colours blended so well, creating harmony in the whole picture. Mr. Stortz’s was the first I ever saw on paper. I don’t grumble, mind. Far from it. But I do think that our societies should enter into these things; and let the members assist in helping them.

For myself, I have the Winsstanley process of pre-lighting, I have my own opal glass, and the Flapper; and those who don’t know what that is send me their address, and I will tell them, and charge them nothing. In this county we have had very bad weather. True, many work with full aperture, with Ross 3, and No. 2B Dalmeyster. I don’t. My weakness is for sharpness and softness combined. I have given the withdrawing the diaphragm a fair trial, and cannot boast of much quickness. My average in summer is twenty-five to thirty seconds; spring, sometimes twenty seconds; but I have now gained some ten to fifteen seconds by withdrawing the diaphragms. Yours, &c.,

AN OLD HAND.

The Studio, Whitworth, Jan. 18th, 1875.

SECRET PROCESSES AND COMMITTEES OF INVESTIGATION.

Sir,—The very excellent suggestion contained in the pertinent observations made by Mr. Young in your issue of the 1st instant, runs some risk of being lost sight of by a misconception of their meaning. Mr. Young’s suggestion was, if I understood him rightly, that fifty good men and true should undertake the examination of new methods which were duly published, and so avoid the necessity of buying secret processes. Mr. Edwards seems to understand that the proposal was, that a committee of fifty photographers should be formed to test secret processes, a thing manifestly impossible. This, Mr. Edwards sees clearly enough, and he suggests that a committee of five trustworthy men would be sufficient to test and report upon the value of a secret process offered for sale. This is probably true enough; but it does not seem very likely that such trustworthy committees will be readily found to undertake such a duty. For whose profit should they undertake such a responsibility? If it be true, as it is frequently alleged, that “secret processes” are generally processes which have at some time been published, and that the work of the “process monger” consists chiefly in working them out to a successful issue, fifty good men and true could do the same with involving any money.

Mr. Edwards rightly says, “we must not always expect to reap the advantage of every improvement and give nothing in return,” but it is a fact that almost every discovery, every great improvement in the art, has been given freely to the public, and the injunction “freely you have received, freely give” is peculiarly applicable to photographers. Having freely received, photographers should be willing to give some time to testing new things, and to give freely the results of their investigations. This is what they should give in return; and if they would adopt the suggestion of Mr. Young, they would have little need for purchasing secret processes. The suggestion in Mr. Hooper’s paper that committees of investigation should be appointed by photographic societies, is a most important one, and well worthy of being carried out.

The note to Mr. R. W. Preston’s letter in your last, seems to cover the entire ground in relation to secret processes. Those who are anxious to obtain the results of the investigations of others, without investigating themselves, ought to be willing to pay for them, and to take the risks of buying a “pig in a poke.”—Yours, &c.,

SBNX.

THE SIMPLEST AND BEST MODE OF ENLARGEMENT.

Sir,—Your correspondent, “A Provincial Photographer,” in last week’s issue, asks me to give a simple and effective plan for enlarging from card negatives to about ten inches, which can be done at a nominal expense and produce a good result. I have much pleasure in communicating the method, in daily use in my establishment, by which such pictures are produced, that it would never occur to anyone to suppose they were enlargements. Of course, I mean, the enlarged plates will not exceed ten inches in size. When you exceed that a different procedure is required.

Procure from Spencer, Sawyer, Bird, and Co. a four-shilling packet of special transparency carbon tissue, and, following the perfectly simple instructions given in their book, or in several places in the News and recent Your Books, print transparencies from the negatives; this four-shilling packet will print about one hundred and fifty, so the expense is not great. No one who once employs carbon transparencies ever goes back to collodion. From this, taking care not to reverse the enlargement, make, by the usual well-known means, an enlarged negative. A hole in the side of the dark room or a cupboard to hold the transparency answers every purpose. Do not varnish the enlarged negative, but cover it with albumen diluted. When this is dry, lay over it back and front the paper vegetal, which may be procured at Messrs. Marion’s, price four shillings and eight pence per quire. On this work, in Mr. Lamberti’s method, as described in your number for October 23, 1874.

Nothing can be more simple or less expensive than this process and nothing more satisfactory than the result. The object in using carbon for the transparencies is because by so doing the lighting and delicacy of the original negative are carried forward to the enlargement, but we all know too well with a collodion positive how opposite is the result occasionally.

If my correspondent will, I am sure, believe me when I say the above method is not theory but practice, and is in successful use every day in my business.—Very respectfully yours,

S. FAY.

Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The last meeting of this Society, held on Thursday last week, was of a semi-public character, there being also a large attendance of ladies. The Rev. F. F. Syntham, M.A., President, occupied the chair, and after the transaction of some routine business, Messrs. Reynolds, J. Hare, Grainger, Cashesdale, and Aslany were admitted members.

Mr. Fay exhibited a print from a negative that had been submitted to the members at a previous meeting of the Society, and some carbon transparencies.

Mr. Spillers exhibited the nitre-sulphur light, and demonstrated
the purity of the flame by means of a card containing specimens of silk of various colours. The fused nitre balls he considered to be a convenient form in which to use the nitrate of potash.

A large collection of transparencies lent by Messrs. Hunter, Young, and others was then exhibited by Messrs. Oakley by means of their magic lantern, and Mr. Gore gave a description of some views in India that formed a portion of the series thus exhibited. The exhibition was very successful throughout, and afforded much gratification to those present.

Talk in the Studio.

ACTIC LIGHT.—The Athenæum says:—"When the vapour of bisulphide of carbon is mixed with nitric oxide gas, the mixture, on ignition, burns with an intensely luminous flame of high actinic power, but of only momentary duration. Mr. Dohachanl and Mermel have, however, recently succeeded in producing such a lamp in which the mixture may be conveniently burnt, and thus applied to photographic purposes. The nitric oxide is generated by the action of iron on a mixture of nitric and sulphuric acids, and after mixture with vapour of bisulphide of carbon, the mixed gases are burnt in a kind of Bunsen's burner, the products of combustion being rapidly carried off by a chimney. For the purposes of the photographer this new flame is said to be superior to that of the magnesium lamp, whilst it is estimated to have twice the chemical power of the oxyhydrogen flame, and three times that of the other light.

IMMENSE PHOTOGRAPHS.—There is now on exhibition in Paris, says the Revue Industrielle, the two largest photographs which have been made since the introduction of the art. One of these photographs represents the principal facade of the new Opera, the other one the facade of the store, by Rude—of the Arc de Triomphe de l’Etoile. Each of these prints measures forty feet three inches in length and three feet four inches in height. They were obtained in one single piece, by long-known processes, and with the aid of a large and specially constructed camera. Except for the size, the effects of the exposure are identical which, perhaps, are not reproduced with absolute fidelity, especially the portion representing the dome of the grand Opera, which appears, on the photographs, to crown the facade including the balustrade, parapet, &c., the lines of the pictures are of remarkable excellence; the mouldings, the busts, the medallions, the inscriptions, and even the minutest details, being reproduced with rare perfection. The attempt is being made to secure pictures even larger than this.

From a Programme of the French Photographic Society. The Polytechnic Institute gives a process by Mr. Willis, as follows:—The paper is floated on a solution of one part potassium-platinic chloride in forty-eight parts of water, dried, saturated with plumbo nitrate solution, 1 to 12, dried a second time, and then washed with solutions of oxalic acid, 1 to 10, and then washed with a solution of nitric acid, a little oxalate has been added to render the iron salt soluble. When dry, the paper is exposed under a negative, and the weak brown picture produced floated on a hot solution of potassium oxalate, which develops it to a deep black. It is then washed in a dilute solution of oxalic acid, next in hot water, and lastly in water. Argentite may be substituted for the lead salt, or platinic bromide with ferric tartrate for the potassium-platinic chloride.

THE PHOTOGRAPHIC NEWS. [January 22, 1875.

W. G.—You will obtain seed lace of any drydressers, or of many chemists or silvers and colourmen. We cannot tell you the price.

BLESTRA.—We do not personally approve of the method of isolating a body by leaving it in a plate or glass, as the action of the dip may proceed from several causes. You will do wisely to make your bath always in the manner which experience teaches you gives immunity from such stromaus. The use of any kind of powder to abrade the leaf, and so obtain a tooth for a lead pencil, involves very great risk, and should be applied only with the greatest skill and care. We never find a trouble in obtaining a tooth for a pencil, or in the direction of abrading powder. Gentle rubbing with the end of the finger, without any powder, will secure a surface on which the pencil will bite. The application of a little turpentine upon the varnish will materially give such a tooth, and will give such a surface. The application of the spirit varnish to the plate without much heat, especially if the varnish has been made very thin by the addition of linseed oil, will give such a surface.

F. W. REYNOLDS.—Many things will, of course, affect the quality of the final tone of a picture; but in your case it is not the paper or the toning bath, but the negative. The print you enclosed possesses, in our estimation, a very good tone; if it had been toned further, it might have acquired its blacker which, however, have become somewhat flat and weak. To permit toning to an intense brilliancy black, the prints must be produced from a very vigorous negative, with strong contrast. If positive prints with strong contrast are to be obtained, the negative must be thin and soft, the best and richest tone it will yield will always be of a somewhat warm tint. If the toning be carried further, it will, in such case, grey, not black. In the case of a negative which is very thin by the addition of turpentine oil, it will give such a surface.

J. NEILSON.—The image appearing on applying the developer, and then at once disappearing, is still, in some cases, a case of fog. Such fog may proceed from many causes. It may be that the solution of the bath, in which case a drop or two of nitric acid will cure it. It may be that the bath is contaminated with some foreign matter, in which case neutralising and warming, or boiling will be the remedy. It may be that the light reaches the back of the room or camera, in which case the remedy is obvious. It may be that the use of very new collodion, or other causes, which must be sought for one another until the right one is found.

X. Y. Z.—The addition of cyanide to a dissolved negative bath is a favourite remedy with many operators, and is often found beneficial. The effect of the addition is the formation of a precipitate of cyanate of silver, which carries down with it impurities present in the solution. It may be used further to acquire a blacker which, however, have become somewhat flat and weak. To permit toning to an intense brilliancy black, the prints must be produced from a very vigorous negative, with strong contrast. If positive prints with strong contrast are to be obtained, the negative must be thin and soft, the best and richest tone it will yield will always be of a somewhat warm tint. If the toning be carried further, it will, in such case, grey, not black. In the case of a negative which is very thin by the addition of turpentine oil, it will give such a surface.

HOPFELD.—Your diagrams are scarcely sufficiently complete to enable us to form a very perfect idea of your plan; but so far as it appears to us to be founded on the principles of your solution, and to promote facilities for obtaining a variety of effects. Blinds and curtains depend much on circumstances. As a rule, we prefer curtains of white or blue calico sliding on wires.

C. MACKEEN.—We have a personal knowledge of what is the most salubrious size of photographic landscapes. We can only suggest the results of observation. Mr. Bedford chiefly produces landscapes of 12 by 10 and stereoscopic size; Mr. England produces whole-plates and stereoscopic size; Mr. Wills, of 8 Parmain, produces stereoscopic and about 7 by 5. These are three of the most distinguished landscape photographers, and we presume that they produce the works which experience has taught them suit the public taste. The subscription to the Photographic News and postage is 15s. per annum.

S. S. YOUNG.—Received. We shall have pleasure in forwarding your membership to the meeting in February. We are obliged by your expression of your good opinion. The Year-Book has been forwarded.

C. A. B.—The iodiser you have used is a very good one, and will do well, if the colloidion, go by satisfactory results. The colour does not depend upon any other cause; the chief advantage of this free iodine is, that it generally aids in securing clean shadows. You may easily produce it by adding a little starch to the colloidion of iodine.

W. T. BICK.—The border is very neat and good of its kind; but we confess to a dislike for ornamental borders to cards.

Several Correspondents in our next.
The Photographic News, January 29, 1875.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

The Thebes Transit of Venus Expedition.—We are glad to announce the return, during the past week, of Captain Abney and his party from his journey to the country abounding in ruins of the ancient empire of Egypt, to the south of the great sacred city of Thebes. The journey, though rough and laborious, was successful in every way, and the returns to the country will be of great value to the scientific world. The results of the expedition will be published in a future number of the Photographic News.

Photography in Courts of Law.—There was a very good illustration in the recent libel case of Rubery v. Grant and Simpson, of the power of photography in affording convincing proof in matters relating to documents. The witnesses were shown photographs of the document in question, and it was proved that the photograph was identical with the original document.

Photographic Transparencies.—There is no more favourable way of looking at a photograph than as a transparency. Take the finest paper print you will, and after admiring all its beauties by reflected light, hold it up against a strong light and see how more plastic and delicate still it appears. Glass transparencies, such as one sees exhibited against windows or upon tables with reflectors underneath, always gain unbounded approbation; and it is really surprising how much detail a hard under-exposed negative has when a print is taken off upon glass and held between you and the light. If we could only find a way of taking a print of a way of showing a little quietness and wood after his labours, will, we hope, speedily restore to his usual strength and vigour.

Process Mongers.—Complaints come to us from abroad about process-mongers who visit provincial towns especially, with secret methods of one kind or another for sale. It is singular that this line of business should be a lucrative one, but such it evidently is, otherwise we should not hear so many warnings and complaints. In Germany, we are told, the travellers give out generally that they come from abroad; and, having got possession of the best importance for sale, and, as a rule, they scarcely ever go away without doing some business. There are, no doubt, some of the craft who deal in bona fide matters, or, at any rate, themselves believe in the value of the method they have to sell; but, as a rule, the secret imparted is one which is to be found in journals, altered a little, perhaps, but not materially. All process, however, like mystery, and the success which attends process-mongers is, no doubt, due in a great measure to their dealing in secrets, the intrinsic value of these being a matter of secondary condition. We do not remember any instance of a photographer having made a good speculation by the purchase of secret information in this way, and for this reason we advise our readers to think twice before they effect a purchase of this kind. Fortunately we are not much troubled in this country by travellers of this sort, who are to be heard of much more frequently in France and Germany.

IMPROVING LARGE NEGATIVES.

By George C灼gton.*

* The print being taken from the printing-frame, is placed against a plate of glass the same size (viz., 20 by 16), and a piece of tracing paper about one-third of an inch larger

Continued from page 3
all round is placed upon it. Now, with the BB pencil, mark out the outlines of the figure, keeping inside the lines. Having done this, the print can be put away till the mask is ready. Next damp the tracing-paper in the manner before described, and place it upon the glass plate, and turn over the edges and fix with strong gum. When the dry film is cut out, or when you want to use it, you can be done upon the tracing paper in the way of light and shade, and even pictorial backgrounds can be put in with the stump and powdered lead, &c.; but with the picture I have been describing I want to put in a dark background relieved by light and shade, with, perhaps, some indication of paneling, and I proceed as follows:—

With a large flat of cotton-wool well rubbed into the mixture of India rubber and bread, a sheet is worked in with the BB pencil, and when the deeper shadow is wanted, then the paper is made more transparent. The mask being now ready, it is placed in a large printing-frame with the tracing paper next the plate glass, the print being adjusted against the glass side of the mask so that the figure is protected, and it is placed out to print. It must be carefully watched, and if some parts want more intensity, a rough lump of cotton-wool is held in the hand and worked about the light from those parts, while the other parts print deeper. If the paneling or any other work upon the background should not be sharp enough, any amount of sharpness can be obtained by varnishing the glass side of the mask with Hughes's mat varnish, working upon it with the pencil for lights and gumming for the shadows. By the use of the both sides of the glass any design can be drawn; but I prefer the indefinite suggestion of detail which is obtained by working only on the tracing paper. It is more in keeping, and makes the background retire from the figure.

If the picture is to be vignetted, there is much less trouble, the figure having been blocked out on the negative, as described in the last paper, is placed in a printing-frame, and a piece of white or a half tinge is laid on the plate. A piece of card is roughly cut to form a vignette, with overlapping piece of tracing paper at the bottom to soften off the drapery. The print from this will be a vignette upon a white ground. This is placed in the large printing-frame, face to the plate glass, and exposed to the light, the face, hands, and any white drapery alone being protected of cotton-wool, and any light and shade put in or modified with a piece of wool kept moving over those parts which need it.

I have lately had an order which has tested this method to the utmost: a 20 by 16 enlargement of a boy in a sailor costume who was standing inside a room with the usual photographic accessories—chair, curtain, &c. The background was faulty and spotty, and in the enlargement the streaks were much too distinct. My customer expressed a wish that the background should be done away with, and something in keeping with the costume introduced, and this was effected as follows:—

The negative having been treated as before described for blocking out all but the figure, I printed just the figure and carefully cut it out with a pair of scissors upon a piece of thin plain photograph paper, and, temporarily attaching the figure of the boy to it as a guide, I put the stern of a boat in place of the chair, and an indication of sea and sky behind him. This was done in a very few minutes with the plumbago and BB pencil. Having taken off the boy, I made the paper transparent by brushing over the back a mixture of alcohol and castor oil, as described in the News some time back. This being placed in contact with a silvered piece of plain paper, was printed, and the result was a paper negative, which, after being toned and fixed in the usual manner, was made transparent in its turn, and the cut-out mask of the boy being adjusted in its place, was ready for printing-in in the usual way. Of course, I found I could improve this paper negative with the powder and india rubber; I used it and I believe it could be done upon the other side of the glass and working upon that. These are little things that experience alone can teach. If I can get to London before the holidays of the societies commence, I hope to be able to exhibit some of the pictures I have produced by this method.

THE ORIGIN, AIM, AND ACHIEVEMENTS OF THE PHOTOGRAPHIC SOCIETY, WITH SUGGESTIONS AS TO ITS FUTURE DEVELOPMENT.

BY GEORGE HOOVER.*

I now come to my second heading, viz.:—"Our claim upon the Government for a money grant and suitable premises wherein to hold our meetings, exhibitions, and have permanent offices." In order to prove the important position held by photography in the various departments of Government, I shall enumerate some of its establishments, its applications, and the benefits derived therefrom.

1. The Ordnance Survey office at Southampton, under Sir Henry James, where zincography has for so many years been successfully practised, causing an immense saving to the country.

2. The Indian branch of the above, under Captain Wadehouse, R.A.

3. Greenwich Observatory, where the declination of the magnet is daily registered, and observations are made by our late President, James Glaisher, F.R.S.

4. Woolwich Arsenal, where all alterations in military drill and equipment, heavy ordnance, and designs of all kinds are photographed, resulting in a great saving of time and expense, such work having been so successfully executed by our President, John Spiller, F.C.S.; and now by our late Secretary, H. Baden Pritchard, F.C.S.

5. The Chatham School of Military Engineering, the photographic department being under our active and eminent Member of Council, Captain Abney, R.E., F.C.S.

6. Again at Shoeburyness, where torpedo experiments are photographed instantaneously, and the effects of heavy shot upon iron plates most truthfully and efficiently depicted.

7. The photographic work at the South Kensington and British Museums.

8. The photographs of the pictures of the National Portrait Gallery [copies of which were sold by the Government at a price that seriously affected the profession, decidedly an error of judgment and tending to depreciate the art].

9. Photographers were considered essential to the complete equipment of our armies during the two late

* Concluded from page 60.
wars in Abyssinia and on the Gold Coast. As respects other benefits derived from photography we may mention the part played by micro-photography and the pigeon-post during the recent Franco-Prussian war. What thousands of families were made happy, both in London and Paris, through photography was far eclipsed, not by the usefulness of the art was in photographing eclipses many years ago, for which an expedition was fitted out under the command of Colonel Tennant, R.E., and Norman Locker.

Photography has done much for science; has furthered art and many industries; has saved the Government and the country tens of thousands of pounds, and (we believe) a serious rupture with a European nation, if the secrets of the Foreign Office were seaward to ascertain the fact.

Surely an art that has done so much for science, as well as for industries, deserves to be recognized by the Government and receive some encouragement in order to further develop such useful investigations.

It is this that inclines me to suggest a call upon the Government not only for an annual grant for scientific industries, but also for promptness in the same manner as our annual Exhibitions, and permanent offices where a studio and all appliances necessary to a good establishment should be found, and instruction given to all desirous and willing to avail themselves of the same.

I now come to my third and last heading, viz.:-The necessity of forming committees for scientific investigation. Why not then, as we report the results of the work of our experimental committee appointed for the purpose, as would be done by the French Academy of Sciences?

I would venture to suggest four subjects that might immediately be placed in the hands of committees, to be reported upon to this Society by the end of the Session or the opening of the next:-
1. Whether a substitute cannot be found for albumen that will secure permanency to silver prints.
2. "How much nitric acid should be used in the negative bath to obtain the best results and secure regularity in working."
3. "Whether a dry-plate process cannot be perfected that shall be as rapid in its results as the present wet process."
4. "Whether, by employing a more sensitive agent than iodide or bromide of silver instantaneous photography may not be achieved."

It is a notorious fact that many minds are at this moment employed working out certain problems: why not make some arrangement whereby these may be brought together? and then we shall assuredly realize rapid and valuable results. There are many here that will bear me out in this assertion, and we have a continual proof of the same; for when anything new and valuable is published some one says, "I was at work at the same thing, and have been for years."

Let us, then, do our best to start these committees at once, and, if possible, have a committee in London and a committee in Liverpool or Edinburgh, work together in the same direction for the same object, and communicate results.

Another suggestion I would make is, "increased sociability." How can this be brought about? Some think by open-air meetings; but I believe John Bull is particularly fond of sitting down. Charitable institutions raise thousands of pounds by dinners; why not try this plan with scientific institutions? It is true we have a chat over a cup of tea or coffee and a biscuit after every meeting; but what is this to an annual dinner with the Prince of Wales or Duke of Edinburgh in the chair? I fully believe in an annual dinner; let it be modeled after the style adopted by the Royal Academy and other societies.

Again, I think it a great pity that evening dress at our annual soirée was ever given up. Let these gatherings be opened with all the éclat possible: it helps to raise the status of the art in the eyes of the educated public.

One suggestion as regards our ordinary monthly meetings. Nothing, we believe, is more interesting to members, or more likely to draw out discussion, than the statement of anything that is new by a practical demonstration of the process. Every possible convenience is given for this to be done; and expense should not be spared. I would just throw out the hint here that if every member brought a lady to our monthly meetings I think it would tend to increase the interest. It is well known that many ladies are greatly interested in the art, and it might be the means of inducing some to join the Society.

Lastly, one word in favour of an annual congress of photographers, and the formation of a "British Photographic Congress." I have both spoken and written in favour of such a scheme as most desirable; and although the Photographic Society of Great Britain has, I believe, more than once proposed it, I do not believe any practical steps will willingly use all its influence to further such a scheme, especially seeing that the photographic department of the British Association for the Advancement of Science is such a failure"—and not unexpectedly so, seeing that photography, as stiil a young art, is only very partially understood by scientific men. They feel and know its importance, they see its results, but cannot enter into its failings practically, or lead to the good land of permanency.

It is one of those pursuits that require constant study as well as a lively interest in order to enter into its requirements and appreciate its usefulness and applications.

In conclusion, I again repeat the resolution it is my intention to move at the next Annual Meeting of the Society, and trust that it may lead to the adoption of some of the suggestions I have thought it right and proper to make. The resolution is as follows:

"That it is the wish of this meeting that the Council shall immediately take into consideration whether it would not be for the interests of the Society to procure a Charter of Incorporation? and also that a special meeting of the Society be called as soon as possible to hear the report of the Council thereon, and pass any resolution that may be necessary in order to give the Council power to act."

DEFECTS IN ALBUMENIZED PAPER; THEIR CAUSE AND PREVENTION.

BY DR. J. SCHNAUSS.†

So long as albumenized paper is employed by photographers in the production of their prints, so long, doubtless, shall we have to listen to complaints regarding it. Practised operators have learnt how to circumvent many of the difficulties that arise, and know how to help themselves on most emergencies. They know that it is not the albumen that is generally at fault, nor the

---

* Since further examination of the subject, Dr. Van Monckhoven no longer disputes Dr. Vogel's discovery.—Ro.

† Extracted from Schnauss's report on albumenized paper.
THE PHOTOGRAPHIC NEWS. [January 29, 1875.

albumenizer, but that, in most instances, the paper itself is the cause of the defects which arise, as also its storage, and the photo-chemical process to which it is subjected. It would be as difficult to find a universal remedy against failures in albumenized papers as to discover the elixir of life, or a medium that would cure all diseases that flesh is heir to. What my colleagues and myself have learnt, however, after years of experience, and by a thorough investigation of the subject, I shall be happy to write down here for the benefit of my readers.

_Speckled Prints._—The tyro in photography generally makes the acquaintance of these phenomena first of all when the prints are lying in the toning bath, observing upon some of them tiny red spots which, as the operation proceeds, become more and more marked; while the print becomes darker in tone, the colour of the spots withstand the action of the toning bath, and are, therefore, after a time, more apparent. They seem to disappear somewhat in the hyposulphite bath, because the tone of the pictures is cleared up a little by the action of the soda.

An experienced printer will detect these spots as soon as he takes the prints out of the pressure frame; a close inspection of such a speckled paper, whether before or after sensitization, is often sufficient to detect the imperfection, before the material is laid upon the negative, for they then appear as matt and brilliant spots upon the surface of the paper. The defects are due either to the imperfect separation from the albumen of fibrous matter, or to the unequal absorption of the albuminous liquid by the paper. According to M. Sterfeldt, the latter defect is caused from the fact that the only two manufacturers of paper of this kind do not keep a sufficient store of the material, and the albumenizers are thus compelled to employ fresh paper, the sized surface of which is not dry enough. Unequal absorption of the albumen, therefore, takes place, and thus the defects to which we have alluded, are caused.

It would be better for this reason never to employ fresh paper, but always that which has been stored up for some time. But even in this case we are not altogether free from our old enemy, for, truth to tell, the same is not always due to the imperfect desiccation of the sizing, and was known long before the question of a dearth of paper in the market arose.

If it is not actually in the power of the photographer to prevent this defect altogether, he can do a great deal to remedy and render it almost unnoticeable. The precautions to be adopted are as follows:

1. Employing a fresh and not too weak silver bath.
2. Careful washing of the prints in clean water before toning.
3. Using a weak gold bath in abundance.
4. The fresher and stronger the gold solution, and the more quickly it tones, the more pronounced will the specks appear upon the prints appear. For this reason baths prepared with carbonate of soda, which are employed at once, are very prone to produce the defects, while old gold solutions made up with acetate of soda, do not produce speckled prints so readily. Especially to be recommended for the purpose is the arseniate of soda toning bath, which is made, up according to C. Durand, of:—

<table>
<thead>
<tr>
<th>Substance</th>
<th>Quantity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Arseniate of soda</td>
<td>20 grains</td>
</tr>
<tr>
<td>Chloride of Gold</td>
<td>1 grain</td>
</tr>
<tr>
<td>Boiling water</td>
<td>6 to 8 ounces</td>
</tr>
</tbody>
</table>

As soon as the mixture has cooled, it may be used for toning. Every time it is employed there must be added to the cold bath one grain of gold and one to two grains of arseniate of soda, after which it is again serviceable within a few minutes.

2. _Blisters on the Albumen Surface._—This is a very well-known defect in silver printing. My own experience, and that of others, proves that it is due entirely to drying the albumen film to too great a degree, the degree of hygroscopic moisture, which the raw paper possessed at the moment of its being albumenized, never being taken into sufficient consideration. These blisters may be prevented very well by taking sufficient precautionary measures, as for instance:

1. Keep the albumenized paper in a damp locality.
2. Mist-ening the back of the albumenized paper with a damp sponge, which must be, like the water, scrupulously clean.

The paper in the latter case is allowed to become slightly again before being sensitized. It must neither be wet nor dried by artificial means before it is floated upon the silver solution, and the latter should be strong and fresh enough to cause the albumenized paper to be treated upon a somewhat riper where alkaline toning and fixing baths are made use of.

3. _The Repulsion of the Silver Bath_ by the albumen film is also obviated by the precautions specified above. It is in the case of a horny and well-dried albumen surface that the repulsion of the silver liquid is most apparent, and it is in weather this disagreeable phenomenon is enough to drive one to distraction, almost. As a matter of course, the defect is apt to appear more frequently in doubly albumenized papers than in those which have received but one coating of the material only. For this reason photographers have recently selected the latter description of paper for portraits, which has, moreover, the advantage of being less costly, a matter of some significance just now; and as the price of albumenized paper is high at the present moment, it is by no means the bounds of possibility that another and better photographic paper may come into commerce shortly, for, among others, experiments made with shellac solution and borax, or phosphate of soda, have not been without some success.

4. _Red Streaks in the Toned Pictures_, which are at once seen due to a deposit of albumen, either by draining or dropping, are very rarely formed in good papers, for they only arise when the albumenizer is not skilled in his work; and, as a rule, sheets that have been spoilt in this way are generally sorted out by the seller. Red spots on the albumen arise from soiling it with your fingers, and must not, of course, be put down to the fault of the paper.

5. _Marked Colouration of the Silver Bath_ is caused by certain albumenized papers. If the silver bath is of an alkaline character, or becomes so after long use, this appearance will not be seen in an abnormal condition except when the surface of the paper is constituted of something besides pure albumen—say of a compound of various fatty matters—or contains such substances as gum, gelatine, &c. The best plan to decolorise such a bath is to shake it up with a little knolín, or to add to it some permanganate of potash until the liquid assumes a rose tint, when it is allowed to stand for some time, being afterwards filtered.

For filtering silver or gold solutions, as also strong acids and alkalies, the so-called glass-wool (fine glass fiber) is to be preferred to paper. A silver bath of normal strength (1:8 or 10) will become discoloured much more readily than a weaker one.

6. _The Discolouration of Sensitized Paper_ is due, in some measure, to circumstances which have already been cited. If you take care not to exhaust the bath, or to allow it to become alkaline, and to shelter the prepared paper not only from light but also from air, the paper may be preserved for some time without becoming brown. A well-stored paper generally keeps well.

7. _Immediate Toning of the Prints_, and a tendency of the pictures to turn grey, is due, in the main, to employing a weak silver bath.

ABOUT THE WET PROCESS

BY PROFESSOR M. VOGEL.

When we look back at the last ten years or so, and study the progress that has been made in photography, we find that
a great many novelties of various kinds have been made known during the period. Thus we have pigment printing, lithoedruck, photo-lithography, and some improvements in lenses to record; but so far as the negative and positive processes are concerned, everything seems to have remained in statu quo. We work now pretty well in the same way as we did ten years ago, and the only progress in this branch consists more in the discovery how to avoid defects, make the work better, and how to get rid of the negative. We work, therefore, pretty well as before, but we do not grope about in the dark so much as formerly, because we understand the operations better with which we have to do. The reproach that was once made against photography, that success was due to chance, does not hold good any longer. We can now, so far as concerns the process itself, guarantee the results as much as a sportsman can predict the effect of a shot.

The operations connected with the positive and negative processes are particularly simple; it is the knowledge how to recognise defects and avoid them that is so difficult to acquire. It is against breakers such as these that the amateur is usually shipwrecked; for as amateurs practice the art merely for amusement, they often leave off as soon as this comes to an end, which is always on the appearance of faults and failures.

The professional photographer is, however, bound to meet all difficulties, and must needs give battle for days and weeks, if necessary, to overcome the difficulties in his path. Only recently a singular instance came to my knowledge. In the studio of M. Schaarhuchter, of Berlin, there suddenly came a time when the developer ceased to perform its office. The negative fogged in a most determined manner when one proceeded to intensity, and became a positive rather than a negative in this. Those who had experienced in the art may remark that such a circumstance as this is not new, but is known to arise when there is not enough acid in the developer, and the addition of this substance would speedily put things straight. But in this case acid was found to be useless, for the same results were obtained over and over again, and there was no alternative but to fix the negatives first, and intensify them afterwards. It was only some weeks afterwards that the true cause of failure came to light. A little hyposulphite of soda had, in some unaccountable manner, fallen into the stock of sulphate of iron from which the developer was prepared, and the operator on whom the duty of making up the solutions devolved, had not remarked the circumstance. But a very little hyposulphite is necessary in the developer to give character to the negative.

Still greater difficulties were met with in another studio here, where reproductions are made, on the occasion of receiving a large supply of Belgian glass. This was offered at a low price, and as many as ten thousand plates were ordered to be supplied. The glass was found to be so impure that, despite treatment with acids, scrubbing, &c., it was impossible to secure a clean surface, and it was impossible to make a print, the glass blurring the image. Thereupon it was then to attempt to clean them any more. The albumening of a glass plate is, however, an operation which, if undertaken in a damp atmosphere, most assuredly bring disagreeable results, and, as luck would have it, the studio in question was very liable to become damp. A continual war had, therefore, to be waged with the bad material, and the operators, you may be sure, were pleased enough when at last they could stand the end to this.

I may here remark that recently the employment of India-rubber and gutta-percha have both been recommended in lieu of albumen. Many local operators, as also myself, have tried a covering of rubber with the best success, so I can recommend its use to everyone, and even to those who employ good glass for their work. It is necessary for the photographer to produce his own rubber solution; but this is not difficult to do, and I doubt it will soon be possible to obtain the same in commerce.

If you want to make the solution yourself, dissolve one part of India-rubber in a hundred parts of chloroform. The pure, soft, so-called natural rubber must be chosen, and this is cut into very small pieces. The material takes a long time to dissolve, and the turbid portion is uppermost. The clear liquid should be secured by means of a pipette, and this is then diluted with ten times its volume of a light pure benzole, such as is employed for glove cleaning. After this care is necessary to pour off the clear supernatant fluid; the clear liquid is secured, which will last a long time and work well. An absolutely clear solution is indispensable for working well.

Gutta-percha solution is more easily made. One gramme of gutta-percha is dissolved in ten grammes of chloroform. The solution is rapidly produced, and then the brown fluid is diluted with one thousand cubic centimetres of benzole and filtered. After a short time the filtrate becomes turbid again and milky. It must then be filtered again. Careful filtration is, indeed, the principal thing to be attended to.

The plates to be covered with this material must be acidified, washed, and thoroughly dried. They are then dusted, and coated with benzole solution, as if it were collodion. The superficial liquid is caught in a separate vessel, and filtered again before use. The plates dry very rapidly, and are capable of employment in a couple of hours; nevertheless it is better for them to remain in a position sheltered from the dust for a dozen hours. They keep good a week.

Sometimes the plates do appear a little grainy, but that does not matter. Before pouring on the collodion the plate is dusted as in the ordinary way.

A photographer of my acquaintance tells me that he has remarked defects in his bath which he believes to be due to benzole. This, however, is highly improbable, for when a plate is stood for a dozen hours there should not be a trace of benzole left, if this is in a pure state. It is, of course, pure benzole that should be employed, and not naphtha. The latter may dissolve rubber more easily, but with the aid of chloroform there is no difficulty in using pure benzole. It is more probable that defects in the bath arise from impure collodion. There are many kinds of collodion in commerce which, besides pyroxiline, contain foreign bodies, of which even the manufacturer himself knows nothing. There is found, for instance, in the preparation of gun-cotton by the action of sulphuric acid a little xyloïdin, nitro-glucose, gum, &c., and these bodies are not to be removed on washing, but remain in the cotton, and being soluble in ether and alcohol come with the collodion into the bath. Every plate that is dipped into the bath increases the quantity of these bodies in it, and so long as they accumulate in the bath to such a degree that they become injurious, and are the cause of streaks and fog upon the plates.

Gunnast made the proposition some time ago to purify the pyroxiline from the by-products by precipitating collodion with water, and thus separating the noxious bodies; and precipitated pyroxiline of this kind did actually come into operation. Unfortunately it was rather dear, but it was bad to work with. Recently the purification of the cotton from its by-products has been effected in a cheaper manner, and the purified materials come into commerce under the name of collodion. I have now employed this material for a couple of years, and I must say that since I have tried it many defects that I used to perceive in my bath have disappeared.

In short, of course, it is necessary to secure pure ether and alcohol for dissolving the pyroxiline. This is a matter often overlooked. It is not unfrequently the case that photographers procure their alcohol and ether from the first best druggist or apothecary, and the purchase may contain, irrespective of water, a trace of fusel oil, which makes sad havoc in the silver bath; furthermore, other times, this contains spirit impurities, which are not less injurious. When impure solvents are employed in the manufacture of collodions, the purest form of collodion is obviously of little use.
THE DISCOVERER OF THE COLLODION PROCESS.

It is somewhat late in the day to renew the enquiry, "Who discovered the collodion process?" The question has been so fully and so publicly discussed years ago that nothing new remains to be said. The question was reopened, in the columns of a contemporary a few weeks ago by Mr. Sutton, who claims the discovery for the late Mr. Bingham, of Paris, whose acquaintance he made a few months before his death, and by whom he promised to give the public the claims in question. If a new claim and a new revelation of evidence were to be made, no one could blame the friendly zeal of Mr. Sutton, even though it involved the mainling of another long-established reputation. But the curious part of the case is, that Mr. Sutton seems to be quite unaware that Mr. Bingham's claims have been published and examined before during his lifetime, and that, unless we are mistaken, he was satisfied with the position in relation to the origin of the collodion process which was awarded to him. We had the pleasure of knowing Mr. Bingham for many years. He generally favoured us with a visit when he was in London, and we invariably visited his studio when we were in Paris. We have had many conversations with him on the origin of the collodion process, and our early experiments in connection therewith. The extent of the claims now made for him by Mr. Sutton, to the effect that he discovered every step of the process from first to last, certainly transcends those we have ever heard from his own lips. Whether Mr. Sutton misunderstood him, or whether his claims became magnified in his own view, we cannot state. Possibly the latter was not improbable, as the lingering disease which terminated his life produced much debility and prostration of both mind and body for many months prior to his death.

That Mr. Bingham was one of the earliest experimentalists with collodion there is not much room for doubt. He was in the natural position to be the first such experimentalist. An assistant in the laboratory of Faraday, where he came into contact with Schönböck, whose experiments with gunpowder were first brought out in this country, he was one of the first who, in this country, saw or made collodion. Being at the same time an ardent photographic experimentalist, and having tried various viscous media for photographic salts, it was very natural that he should early try the new substance which Schönböck's discovery gave to the world. That he did so, but with indifferent success, we have heard from his own lips; but that he discovered every step of the process as Archer published it we never heard him state. The priority of his suggestion, and the circumstances which attended it, we published, on the basis of evidence with which he furnished us, we published some years ago, and the extent of our claim on his behalf, we had subsequent reason to believe, met with his approval.

The priority to Archer's publication of Le Gray's claim for suggestion is also beyond question, and equally beyond question its vagueness and unpractical character. That he himself had no faith in it is manifested by the fact that as late as 1853, when the collodion process was becoming popular in this country, Le Gray published his conviction that the future of photography rested on the paper process as giving finer negatives than glass. The early experiments of Bingham and Le Gray, both of them photographers of the highest ability, were, so far as they are on record, crude, imperfect, and immature. It was the collodion process, published in a tolerably definite form, of Archer which rapidly gained popularity, and which with comparatively little change, is the collodion process of to-day. To what extent Archer might have been indebted to Mr. Bingham we cannot tell; we never heard Mr. Bingham claim more than the earliest use of collodion. From enquiry amongst intimate contemporaries, we cannot learn that Archer and Bingham ever worked together at all. That Archer was greatly indebted to some of their suggestions for the collodion process, and that working the process into shape there is to doubt. Mr. Diamond was one of the most successful of these, and produced presentable pictures by means of the process with which he, in conjunction with Archer, experimented. But none of these things detract from the fact that Archer worked his process into shape; Archer gave it to the public, and with his name it will always be legitimately associated.

ALUM FOR ELIMINATING HYPOSULPHITE.

The plan of using alum for eliminating hyposulphite from prints after fixing, proposed by Mr. Clemons, continues to attract attention in the States. Whilst many speak in the highest terms of its value after test experiments, others complain that it spoils the tone of the prints. It will, doubtless, have a bleaching or reducing action upon the print; but if it be found in practice to have a valuable effect as regards permanency, it would not be difficult to print and tone deep enough to prepare for the reducing effect in the image. It must be borne in mind that as yet but little testing time has elapsed, and that theoretical reasons render the issue doubtful. Mr. C. W. Hearn, writing in the Photographic Times, after protesting against the habits of photographers of only half testing new processes, is not adhering to early experiments in connection therewith. Mr. Clemons recommends for his directions in using the alum bath the following:—"In the first place, he advises the use of a saturated solution of the alum, and to let the prints remain in two minutes at a time, and then rinse the alum off, and place them in again for three separate times, and then rinse and wash for a minute or so, and mount." Now you may ask, "What is all this fuss about, and what is that, me, you know, going to say anything yourself concerning it?" Now this "fuss" is for the purpose of drawing other photographic printers out, and to give the fraternity at large the result of their experiments in this affair, and as to myself, I will simply give the result of a single experiment, which was simply an experiment of permanency of print, more than it was for the beauty of tone.

About the 1st of August, by request of Mr. Clemons, I gave the alum a trial, as follows:—After I had fixed a batch of prints, I took therefrom a couple of cartes de visite, rinsed the superfluous solution from them, and then without any more ado, I placed them in a bath of alum for the space of ten minutes, and then rinsed the alum water off from them, and set them away to dry over night. In the morning I took them from the washing tank two other prints, which had been washing all night, and marked on the back of the respective prints the precise manner in which each one was treated, and then tackled the four cartes side by side in a part of the printing-room where
the sunlight falls many hours during the day, and yet, now these prints, after having remained there fully five months, show no indication whatever of the least signs of fading, the album prints standing the test equally as well as the prints which were washed all night.

Now while my experience does not date further back than the 1st of August, yet I have received letters in which I have been informed that some persons have used it constantly for over a year, and in my next I hope to be able to give other notices of the permanence of the prints which have been subjected to the album bath. Many photographers cry against the album destroying the tone of the prints, my experience seconding the same, but Mr. Clemens informs me, in a recent letter regarding it, that he had no difficulty in obtaining fine tones. But knowing nothing further in that line at present, I will not write further about that; but if Mr. Clemens will enlighten the fraternity in that particular, I think that I will speak for them all in saying that he will thereby remove the loudest cry against it. In the meantime, I believe we all, I myself at least, would like to hear from other photographers who have used this album with or without success, and I am sorry to this present there is no brilience in the appearance of the finished prints treated with the album bath, for the purpose of eliminating the hypo, and which have undergone but little, if any, washing worthy of mention after fixing.

FRENCH CORRESPONDENCE.

MM. BISSON ET FRERES, THE WELL-KNOWN PHOTOGRAPHERS.
—IMPROVEMENTS IN DRY PLATES AND APPARATUS FOR TRAVELLERS.—THE EARLY DAYS OF CARBON PHOTOGRAPHY.—RECENT IMPROVEMENTS.

Some days ago I received a visit from M. Bisson jun., whom I had not seen for some considerable time. There is scarcely a reader of the Photographic News, I feel assured, who has not heard the name of this skilful photographer, who, since the birth of our art, has always been in the van, so far as regards improvements and progress. Bisson, who for a long time has been associated with his elder brother, acquired a European reputation, in the first instance, by the grandeur of the works he produced, when masters in the art were but few. When the colloidion process was first of all practised, MM. Bisson Freres produced pictures a metre long, which were as astonishing to their brethren as they were to the public. After having travelled through Switzerland, and secured views of all kinds, which were not only admired by the traveller, but also much appreciated by scientific men, they had the hardihood to scale the most inaccessible peaks with dark tent and camera, and perform feats which seemed altogether insurmountable. Three times was the ascent of Mont Blanc made, and panoramas produced such as are to be perceived only at that height, together with other clichés of interest taken en route between earth and sky.

Later they made, no longer on their own account, but upon that of M. Levy, the well-known stereoscopicist, twice successively a voyage to the East, and brought back some charming views of that fairy land that goes under the names of Constantinople, Greece, Egypt, and the Holy Land.

In their early part of their career, in order to render the art more easily applicable in long journeys, &c., MM. Bisson completely modified their methods of operating. A deep study of the albumen process was made, which lends itself better to long voyages, and they made themselves master of all the difficulties that presented themselves. Experience showed them the inconvenience of being encumbered with much baggage, and proved that the travelling photographer should have the most simple apparatus and most simple process to work with.

Having resolved the problem for themselves, M.M. Bisson frères have now the idea of giving the key thereof to their colleagues, both professional and amateur, offering them plates already prepared, and a travelling apparatus constructed upon the most simple and approved methods. In the visit just paid me, M. Bisson, jun., explained all this, and exhibited some specimen plates which he has prepared, and a model of the apparatus he has invented. The plates shown me were of the most delicate nature, such as only a well-versed practitioner could have secured, and the results are truly marvellous. M. Bisson assured me, too, that they may be employed with great certainty, and without fear of those irregularities in manipulation which often cause so much disappointment to those who employ dry plates purchased in commerce.

As regards the apparatus, I may state frankly that I have never seen anything so simple or perfect in construction. In its ensemble it much resembles the scéenographic, which I described a short time ago in these columns; but it is seen at once that only a master in the art could have designed so perfect an apparatus as this is. Thus, by way of example, I may say that the frames in which are placed the sensitive plates are veritable masterpieces of adjustment; and, notwithstanding their lightness, two plates find place in very one of them, fixed back to back. They are mounted by a twist of blanched linen, so as to secure two plates it is only necessary to reverse the slide.

There is not a portion of the apparatus which does not work with mathematical accuracy, and yet, despite the fineness of workmanship, the price does not exceed that of the Dubroni playing which is sold about France to the students and schoolboys.

In short, of course, I will give further details about the plates and apparatus on a future occasion, confining myself to this brief description until M. Bisson has definitely concluded the arrangements he is making respecting them with the principle photographic dealers in Paris.

In 1862 Poitevin put a finishing touch to his process of printing in permanent pigments which he announced that his method was now in practical condition, and he was prepared to grant licenses to such professional photographers who might desire to practice the art. There was only one applicant in Paris for permission to work the process, and this was M. Pierre Petit. As soon as he had acquired the right of working the process from Poitevin, Pierre Petit caused to be painted on the walls of his establishment in letters two metres high an announcement which he believed would attract crowds of customers. It was to the following effect:—Imperishable carbon photographs. At the same time he showed the lessons given him by the inventor. But Poitevin, to whom photographers owe so many ingenious discoveries, and who knew so many of the theoretical secrets of the art, was himself a very mediocre operator, and could not practice what he preached. Moreover, his method required those improvements and simplifications which only continued practice in the art day after day could bring about, and consequently Pierre Petit was compelled very soon to lay aside his enthusiasm. Again the public did not yet understand what photography in carbon was, and did not therefore bestir themselves to demand those imperishable photographs of which specimens were shown them, specimens which scarcely gave a favourable idea on the subject. Things, therefore, continued on in the same way, and Pierre Petit, like his neighbours, continued to give his customers portraits, more or less permanent, printed by the aid of silver salts.

Since that time a dozen years have passed away, and, despite the great and persevering efforts that have been made, carbon photographs have remained out in the cold, having failed to make way into our studios. But there is now, we are glad to say, signs of the process reviving, for it is making its appearance in the studios. Among these may be mentioned Pierret at Braun, Franck de Villecholle, Liébert, Walary, Truchelet, &c., all of which have made arrangements for this new
method of printing. In a short time, doubtless, the public, which has now scarcely made up its mind upon the subject, will have nothing more to do with any prints excepting those produced in permanent pigments. For it must be admitted that the portraits which have been seen in the photographic studios which we have been referred to are far superior to pictures which are produced in the ordinary way by silver printing. Therefore, it may be the sad commentary of our generation that we are now on the eve of that revolution which has been anticipated for many years past, and for one am not sorry it is coming to pass.

ERNEST LACAN.

COMETS AND SPOTS.

BY W. J. STILLMAN.

I have been making some studies on comets and spots, in emulsions especially, and find that the worst cases, and a large proportion of all, come from impurities on the plate, either held there by a substratum, or falling on the plate in coating, particles of dust of chemical nature, or impregnated with chemical substances. In wet collodion, it is easy to eliminate the effects of the solvent held in suspension in the developer, which will sometimes adhere to comets, with other causes of the same defect, because the flow of the developer follows pretty much the same law as that of the collodion, and it is customary to connect the curves of comets or the direction of their flight, with the flow of collodion or developer. If the developer contain particles of any chemical reagent capable of reducing silver from the nitrate, the comets are due to the connection of so-dry a solution of emulsions that the developer is often cast on by aqueous solutions, the surface of the film and carried by the developer with it. These last are generally very small with short tails. With a carefully filtered bath, and an old developer (several days at least) carefully deposited, there will be no danger of comets from either of these causes, and they are rarely those to which the trouble is due. In dry-plated development, especially, we have nothing to do with developer or bath comets, and yet comets are more common and graver nuisances in dry plates, particularly emulsions, than in wet collodion.

A careful examination of many negatives by different dry plate processes convinces me that the principal or most disastrous cause of comets, opaque specks, &c., is the albumenizing process, where the film is dissolved in the substratum. If these particles are readily soluble in alcohol and other solution takes place at once, and the dissolved chemical follows in a line in the direction of the flow, the action being strongest towards the nucleus of the comet. If there is free silver in the emulsion or the developer, of course there is a line of reduced silver in the negative, if not, and the chemical particle have a reducing power, as, for instance, a particle of carbonate of soda, there is a more energetic reduction as soon as the developer is poured on, with the same result. Sometimes the comets will head in opposite directions, which shows that there were numerous particles both fixed on the plate and lying on it, in the former case the line of dissolved chemical following the flow and leaving the nucleus behind it, and in the latter the nucleus moving on with the wave of collodion, and leaving its track imprinted with its substratum.

In using the Liverpool washed emulsion, I have found one lot of plates marked by comets and transparent or opaque spots, and another lot, prepared from the same bottle, perfectly free. When coating these in my room at an hotel, I found them usually very free from specks, so long as I used no substratum; while plates coated in a room used for photographic purposes, or which had been previously coated with albumen in such a room, were liable to all these defects. In these plates, though there is no question of free silver, there is also no chance of washing out the chemical once entangled in the film; and therefore, while comets are very rare, transparent and opaque spots are very common when the substratum is applied in a room where there are chemicals, especially alkalis—soda, potash, or salzes from the grate—floating in the air. Plates coated with the Liverpool Co.'s emulsion with no substratum, but simply a border of india-rubber, were the most free from specks of all kinds of dry plates I have ever used; while others which had had a coating of albumen applied in a Zombies were the same, but a slight hill and a light ridge, this was now on the eve of that revolution which has been anticipated for many years past, and I for one am not sorry it is coming to pass.

I was lately called in to advise on the remedy for an occurrence of specks and comets in the Liverpool Co.'s plates, and, after examining emulsion, water, preservative, &c., &c., without finding any fault, I discovered a specked emulsion in the albumenizing room which caused the specks. For coating spoiled plates to remove the old film, and in which the soda had dried in efflorescent crystals over the edge of the dish, the plates in it, &c., in such a way that the least touch would set about small particles of soda which might readily attach themselves to the wet albumenized plate. Soda, and every form of chemical substance not in bottles, was at once banished from the room.

When the spots are transparent the dust attached to the substratum would of course be of such chemical nature as to produce insensitiveness; and this spreads as the plate is kept, so that plates which showed no spots when first prepared would show large disks of insensitiveness with a centre of foreign substance. When plates are thoroughly washed this is washed out, but in lightly washed plates, and especially in the washed emulsions which receive no washing in the film, these spots are exceedingly troublesome unless proper care be taken to avoid dust.

There is a form of spots recognizable enough, and known by all wet collodion workers as the result of too much of some slightly soluble salt in the iodo-bromised collodion, which may be pitting, when one thinks that the collodion has been thoroughly deposed before using, and that all particles of salt have settled to the bottom. The reason is, that as the solvents hold in solution all the salt they were capable of holding, the moment they begin to evaporate the salt gathers together in minute crystals in the film, and when the plate is dipped in the bath they re-dissolve, impregnating the film for a small distance round with a greater amount of salt than the average film contains, and produce spots of insensitiveness, and transparency in fixation.

Correspondence.

THE "VEXED" QUESTION.

Sir,—The championship of a dying assertion, undertaken by Mr. Sutton in the British Journal of January 1st, although bearing testimony to his humanity is not the less extraordinary on account of the total absence of dates, or, indeed, of any single fact connected with the case, except that of extolling the genius of one man by depreciating that of another—certainly a most illogical method of proof. Mr. Sutton bears hard upcn Archer and seems to indicate he was ignorant, inscientific, and in fact accuses him of every fault a photographer ought not to possess. Wanting a personal knowledge of Archer (which might give rise to partialities) a just decision of his abilities might be grounded upon his published contributions to photography. In the May number of the Chemist, 1850, Archer pointed out the energetic qualities of pyrogallic acid. This, in
itself no mean contribution, and paves the way for that celebrated article detailing the whole of the collodion process, with but few alterations such as practised to the present day. 

As I shall have more to say respecting this claim, I merely at present give the date of publication, the March number of the *Chemist*, 1851.

Le Gray published a "Manual of the Collodion Photographic Process," in which was given a more elaborate explanation of the manipulatory details than could be contained in the *Chemist* of 1851, and the directions in the Manual are at once concise and practical, and the book in its simplicity, would hold its own against any treatise of the present day. 

The following is a paragraph selected from the Manual, page 22:—"The advantages gained by using a stronger bath of nitrate of silver do not, in my experience, counterbalance the increased expense, I shall therefore give the old proportions thirty grains nitrate of silver to one ounce of water—as being the most economical, and giving the least trouble." After a lapse of twenty-two years from its publication, can the present generation of photographers say much the same? This is but one of the practical hints treading in the "manual" hand, nor can we pass over the writings of Archer, or his means of information most cruelly misdirected, to apply to the labours of Archer expressions, (even were he living) at once harsh and unjust, but being dead, becoming doubly so.

On comparing the dated publications of Bingham, the communication of Mr. Sutton respecting his (Bingham's) "dynamic" observations of 1843, and the collodion, receives a remarkable degree of corroboration. In all, eleven editions of "Bingham's Photographic Manipulations" have been published, the last in the year 1854. On carefully comparing several preceding editions, the practice of the publisher evidently was to issue an edition every year as follows:—seventh, 1850; eighth, 1851; ninth, 1852; &c. If this sequence was always followed, it would carry Bingham's "Manipulations" up to 1843. This is, however, begging too much of the question. The only edition I can speak of, is the seventh, 1850, January, in which Bingham, enumerating his experiments, mentions amongst them collodion. The communication is meagre in the extreme; meagre though it be, it is sufficient to indicate that the mention of collodion for photographic use is incontrovertibly due to Bingham. It is impossible to account for the fact that, as far as known, Bingham never published any protest against the claims of Archer, though during the issue of the last two editions of the "Photographic Manipulations" the collodion process was rapidly rising into commercial value. In Archer's preface (page 7) to his "Manual" of '52, he observes that G. Le Gray was the first who "alluded to collodion, and then only "incidentally as a substance that might possibly be made available;" further on remarking "that their experiments [Le Gray's] I suppose one of them produced no result."

To give an idea of what Archer terms "incidentally" and "no result," the following Appendix is copied verbatim from a "Treatise on Paper and Glass, by G. Le Gray," published by Villate, Ironmonger Lane, translated by Cousins, date 1850—one year previous to Archer's publication in the *Chemist*. 

Appendix.

I have just discovered a process upon glass by hydroxyoic ether, the florides of potassium and soda dissolved in alcohol 40° mixed with ether, and afterwards saturated with collodion. I afterwards remove the surplus of silver in the camera in five minutes in a shade. I develop the image in a very weak solution of sulphate of iron, and fix with hypo-sulphite of soda. I hope by this process to arrive at great rapidity. Ammonia and bromide of potassium give great varieties of promptitude. As soon as my experiments are complete, I will publish the result in an Appendix. This application upon glass is very easy. The same success is obtained with albumen and dextrine give also excellent results, and very quick.

I have also experimented with a mucilage produced by a fascia—a kind of seaweed—which promises future success. I hope by some of these means to succeed in taking portraits in three or four seconds.

For the credit of the memory of Archer, it is to be sincerely hoped that he never saw the above appendix, as otherwise it might raise in the mind a painful suspicion of ungenerous repudiation.

It is in the appendix is not solicited upon the vague assertions of an unknown name, Le Gray's was an established fact in photography, stamped in after years by productions of bold practical originality. Here are given collodion, ether, alcohol, sensitizing salts, developer, and fixing, and the specified times of exposure would credit modern practice.

By what possible arguments, can the advocates of Archer's claim, ignore the above overwhelming proof of Le Gray's priority?

The above date (1850), but represents the translated edition, but so fully convincing is this translated appendix, that any further investigation respecting the date of the original matter was considered useless, though I strenuously oppose Archer's advocated priority, no doubt that when collodion his name will be invariably connected with. This contribution to the *Chemist* is a "Manual" and the above gave such an impulse to photography, that it is felt to the present day. Following is a tabulated view of my idea of the invention:

Date, 1850, seventh edition of Bingham's manipulations, mentions, amongst the experiments, the use of collodion.

Date, 1850, Appendix in Le Gray's work, mentioning the "Manipulation" of Archer, April.

Date, 1851, Archer's communication respecting the energetic power of pyrogallic. Date, 1851, Archer's communication to the *Chemist* on the collodion process. Date, 1852, issue of the Manual by Archer.

Sedulously in the above, all family affairs have been avoided, trying, if possible, to draw from the dotal balance some approximate solution of a "veiled" question.—Yours truly,

H. Burtman

IN THE MATTER OF SECRET PROCESSES.

In the photographic mind, there is somehow an aversion to the sale of secret processes. Yet why should it be so? If a man can do something you cannot, and is willing to impart his skill, the knowledge to you, do you suppose to some recompense, no matter if the method be new or old.

The schoolmaster teaches nothing new, and it would be quite illogical to dispute payment with him because the information he imparts has been previously published, as to quarrel with a process dealer because he points out and proves advantages you hitherto have been ignorant of.

Now as "Sennex" quotes "Freely ye have received, freely give." Photographers generally are willing to take and continue to freely receive. But what about the giving? What did Scott Archer receive? An amount less than that since asked for an enamelling process. What did Goddard receive? What did Blair? Blair who did as much for carbon printing as any other known man, and gave his experience freely; why the fraternity gave his survivor a sum he believe under ten pounds. Be it as it may, a couple of thousand pounds will cover all the brotherhood has ever given, out of their wealth, to those poor experimentalists upon whose brain-work their fortunes have been built.

With examples like this before you, photographers have the assurance to point to those whose names are struck off our mustard-roll, and barfacedly say to modern experimentalists, "Freely give," ought they not rather to hide their heads in shame.

Let him, who next quotes this saying, say what he has received and given, and I do not doubt upon whose side the balance will rest,

W. E. B.

Halifax, January 25th.

[Our correspondent "Sennex" must answer for himself, if he think proper, the argument of "W. E. B." but we may]
A PERSONAL EXPLANATION.

Sir,—I venture to ask a small amount of space in your paper in consequence of the very great number of letters I have received since the issue of the ALMANAC, and which are all on the subject of the last three or four years' work in collodion-bromide. Many ask that I should at once publish all the results of my experience, and many go back to the old discussions that took place in 1871.

It will be remembered that in June of that year I read a paper on Collodion-Bromide before the Photographic Society. I proposed a very great difference in the manner of making an emulsion from what any previous writer had done, and I showed on what point previous workers had been in error.

No sooner had my paper appeared than I was instantly attacked, and I was told I was all wrong. Knowing I was right, and feeling the importance of the modification I had proposed, I resolved to submit plates prepared in the manner I proposed to the crucial test of public opinion.

How far I succeeded in proving my case may be judged from the fact that all who really understand emulsion work (Ganon Beechey, Mr. Stillman, Mr. Mawdsley, Dr. Dawson, Mr. H. Cooper and others) agree with me, and I now find it would be a bold man who would propose to make an emulsion with ten grains of silver only to the ounce, or who would attempt to uphold the doctrine laid down by Mr. Carey Lea, previous to the reading of my paper in 1871, that any excess over ten grains was "not only useless but injurious to the emulsion."

Having, then, as I believe, clearly proved my case, I drop collateral photographic as far as having any necessary interest in it goes, and can answer all the letters by saying that at any time you have any point that my experience may assist to elucidate, I shall be most happy to contribute my mite.

I cannot conclude without thanking the numerous professional and amateur photographers who have helped me with sympathy and advice. I believe that in the ranks of the profession, as well as among amateurs, I have made not a few friends, and if one or two patents one or two persons whose trade instincts I have offended have constituted themselves my enemies, and dislike my having written and published all I know, pro bono publico, they are, happily, in a very small and powerless minority. Yours, &c.,

H. STUART WORTLEY.

DALLASTHY.

Dear Sir,—I have not had time till now to thank you for your favourable notice of the bijou reproductions of the PALL MALL GAZETTE and FUN ALMANAC. But you have made a mistake in the name you have given the process. The little things were not done by my photo-electric process, which, as you know well, produces an intaglio plate for copper-plate printing—a process I have, much against the grain, long ceased to work. They are done by Dallasthy, which is a quicker and cheaper process, intended, as you are also well aware from specimens you have seen from time to time, to produce, as blocks for surface printing and other purposes, enlarged, reduced, or same sized copies of woodcuts, type, or MS. matter, line work in pen-and-ink or pencil, chalk grain and steel or copper-plate prints, and lithographs in line. This is the process I am making arrangements to divulge to subscribers on easy terms, which will be shortly published.

"While I am on my legs"—or, to be literal, calamares—"I find myself compelled to decline an honour thrust upon me, not without covert sarcasm. An article on the so-called Prettach process, by Herr Leipold, has been translated in your journal. In that article Herr Leipold describes me as the only disciple of Prettach, and writes as if Dallasthy and Prettach's process were identical. I am neither Prettach's "consequence," nor is Dallasthy Prettach's process by name. It is physically impossible to apply Dallasthy to the Prettach process.

[Mr. Dallas proceeds to refer, at considerable length, to...]

J. MACAR WRIGHT.
other articles by Herr Leipold and Herr Scammoni in a Continental journal, in which he revives the old discussion as to the respective claims of himself and Herr Preischl. Mr. Dallas uses strong language, charging Herr Preischl with "robbing him of the fruits of his brains"; but as the matter has been discussed before, and has scarcely now even sufficient personal interest for recapitulation, we do not feel justified in filling several columns with its revival. We give the conclusion of his letter, in which he gives his estimate of the value of the process recently described.

And after all, what is the so-called Preischl process now worth? Herr Leipold has, I admit, given the most lucid description of it which has yet appeared—more lucid than the inventor’s patent. Yet, as I have said, what is it now worth? It is too expensive, too roundabout a method of photographic engraving. It is a mass of uncertainties and complexities, even on Herr Leipold’s own showing. It is not possible to produce by it uniform results, and it requires expensive skilled labour (Herr Leipold says nothing of what the engraver must do) to make its productions presentable works of art of even moderate calibre.—I am, dear sir, yours truly,

DORCY C. DALLAS.

925, Gray’s Inn Road, London, January 30.

NITRATE OF BARYTA.

Sir,—I do not know whether Mr. Henderson, or any other of your readers who uses nitrate of baryta in the negative bath, has ever observed any peculiarity in the behaviour of that salt, when added to a solution of nitrate of silver.

I have lately been preparing some baths for the coming summer—baths mostly old, which had been neutralised, boiled, or sunned, and filtered, and stored away in a south window during the late autumn and winter. They had been neutralised and boiled, retained their apparent purity, no deposit on the bottle, yet when powdered nitrate of baryta was added to it and well shaken up, in a short time a lavender, or some such tint, was observable, which lasted some hours. The second, neutralised, sunned, and filtered, with a slight deposit on the sides of the bottle, showed a much deeper stain. This was a new bath last summer, used only once out of doors for a few plates. The third, a remade bath from carbonte of silver, had the faintest discoloration. All these baths, of about 40 oz. each, were originally made with rain-water, collected in the open country in glazed earthenware vessels.

I have used throughout Mr. Henderson’s formula; viz., three grains of nitrate of baryta, and after complete dissolution, allowing the grain of influence to sink to the bottom of the bath. They are all now clear and bright, but I have not yet tested them. Now, sir, the moral I wish to draw from the above is this: if the lavender, or other tint, indicate the presence of organic matter in baths carefully treated, not over used, apparently pure and which had been working well before being laid aside, it seems to me an additional merit, beyond the great benefit the nitrate of baryta confers in greater stability and greater sensitiveness and endurance, if it can thus eliminate all hitherto unsuspected evil from the silver bath.

As I am now seeking information, I should be much obliged if Mr. Henderson or others will take the trouble to confirm or refute the observations I now venture to submit to your notice. I may add, the nitrate of baryta was obtained from a well-known chemist, and is, therefore, presumably pure. Your obedient servant,

R. M. S.

FUTURE PRESIDENT OF THE PHOTOGRAPHIC SOCIETY.

Sir,—As one of the founders of the Photographic Society of London, and one of its old officers, I have watched with interest and anxiety its history during the past year. The prospect of renewed peace and prosperity should be very satisfactory to those really concerned about the welfare of the society. As the confirmation of these prospects must depend very much I think on the choice of officers at the coming election, will you allow me to suggest to those of your readers who are members, that those most likely to conserve their interests in the future, are those who have served them well in the past. For many years, through a perilous period, Mr. Glaisier proved a highly valuable President, and I believe his re-election to the Presidency would be of the utmost benefit to the Society. It would also be a graceful recognition on the part of members that his good services were remembered, after the bitter feelings of temporary agitation were forgotten.—Yours most truly,

HUGH W. DIAMOND, M.D.

THE FUTURE OF PHOTOGRAPHY.

My Dear Sir,—Mr. Hooper’s paper read at the last meeting contains many valuable suggestions, and points to a very distressing state of affairs in the history of the Photographic Society. A sort of revival is absolutely necessary, and it behoves all concerned to lend a helping hand. I hope that photography is now old enough to do for itself what it has been accustomed to expect from a different source, and unless the profession is made aware of its duties, the decay, now only too apparent, will go on, and there is no saying what may be the ultimate result. In the absence of any genial spirit willing to come forward and expose himself to the insults of the lookers on, we must look for help from the photographic press, and there is now, I think, a capital opportunity for putting practical suggestions to the test. A Royal Charter and Diplomas are visionary expectations. The profession ought to support its own society, and support it liberally. One hundred of its most successful members could easily be found, who might be induced to subscribe five guineas annually, and engage further to pay such subscription for five years. Such an income might, in addition to other sources of revenue, place the Society on a safe footing, and considerably extend its useful press.

It is much to be regretted that among its attributes the Society has not that of giving its decisions or opinions on matters which concern the art, brought from time to time before the photographic world by its professors; such a course might save much annoyance and ill-feeling to all concerned, and put an end to dirt-throwing, of which there has been a great deal more than is necessary or profitable. The last instance to which I should like to call your especial attention is the "Kennett discussion," when the word "stolen" was persistently repeated. If it has come to pass that all works marked "St." are likely to be accused of such a charge, and to be allowed to use such language towards any one who may bring the result of his labours forward for the benefit of the fraternity I can only predict very disastrous results for all concerned. I can easily understand why the most successful photographers keep to themselves most things which they might otherwise feel inclined to make public for the benefit of others.—Yours very truly,

C. FERRANTI.

January 18th.

Proceedings of Societies.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The ordinary monthly meeting of this Society was held at the Memorial Hall on Thursday evening, the 14th inst., Mr. W. T. MAHLEY, President, in the chair.

After the routine business, Mr. John Boar, Jun., read a paper entitled "A Few Remarks about Silver Printing" (which will appear in our next), and exhibited a number of prints in illustration.

Mr. Brothers, F.R.A.S., said that as photography had been employed in the recent transit of Venus, he thought the members would be glad to know in what way the photographic methods had been made useful; he then, by means of a large number of diagrams, illustrated the whole subject of the transit, and con-
THE PHOTOGRAPHIC NEWS.

(JANUARY 29, 1875.

W. W.—An autotype negative may be used for producing silver prints, the same as any other negative. 2. We cannot speak with the facilities of the rapidity of the autotype as to producing large heads, not having made comparative trial.

A. K. L.—It is somewhat difficult to advise you without knowing how many prints you have any reason to make. It is a good plan to make the prints in a dark room, and also knowing whether it is required for occasional or frequent practice. If for occasional work only, one of the numerous dark tents or dark boxes might be used; if for frequent use, it would be wise to make a frame-work of wood and cover it with a double thickness of black calico. The disadvantage of this would be the tendency of all kinds of fabrics to harbour dust, and the risks which attend dust in a dark room. Can you spare a space in any room which will admit of a wooden partition to make a dark room of four or five feet square. If so, that will undoubtedly be best, and might be easily and inexpensively managed.

JOHN STONE.—Some years ago we had considerable success in electrotype experiments, but not recently. We regret that we cannot help you in your difficulty, as we do not remember meeting with any similar case.

AMATEUR PHOTOGRAPHER.—Your examples of work are very good—the landscapes especially. The portraits are good, but the lighting is not quite satisfactory, that of the lady especially, in which the face is flat from the use of a direct front light. The most defect is the white sky in the unmoved landscape. The snow scenes are effective.

COMMEN. —Much depends on circumstances. The following are good proportions:—Length 28 feet, breadth 12 feet, height at eaves 6 feet, height at ridge 13 or 14 feet; north side and roof 3 feet opaque, south side and roof 2 feet 6 inches, and the remainder glass, to within 20 inches of the ground; south roof opaque, south side about 10 feet of glass. 2. The less you mention may be used for cabinets; but if required for full-length figures it would need a small cabinet, and this would be in consequence of the smaller area on which to work the process, now a secret, will be sold for a price which will be duly published.

We fear that the practice of photo-mechanical printing is too limited to induce dealers to keep any extensive stock of such materials, but there should be no difficulty in obtaining them when required.

R. B.—Plain prints may be produced on the unsigned side of albumenized paper; but so small a size as plain paper properly prepared. The paper should be floated on the ordinary silver bath with the albumenized side in contact with the solution. The toning and fixating may be conducted as usual. We have seen very good prints so prepared, and they are as useful in photographic purposes as any other of the usual method.

2. It is possible, by applying cuttlefish powder to the face of an albumenized print to secure a surface upon it to work with crayons.

M. K. L.—There are various modes of ascertaining the equivalent focus of a portrait lens. One of the most simple is that which we proposed many years ago. Take any flat object—say an engravings or diagram—copying or drawing on it, the image of the equivalent of the original is obtained upon the ground glass. Now remove the lens and measure the distance from the ground glass to the object; one half of this distance will represent the equivalent focus of the lens.

G. M.—No report has yet been made.

J.—It is probable that the process of enamelling prints will tend towards permanence, and may be a great advantage to the image from atmospheric action. Waxing, and treating with the various enamou paste will extend to protect the image.

PROVINCIAL PHOTOGRAPHER.—If our correspondent who used this signature a fortnight ago will communicate with Mr. R. Passmore, of Swindon, that gentleman will furnish him with some albumen plates which will suit his purpose.

B. E.—The best method of adding intensity to a varnished negative, in our experience, is that which we described many years ago. It consists in treating the negative with tincture of iodine, made by dissolving eight grains of iodine in an ounce of alcohol. First mounted the varnished with plain alcohol, and then apply the tincture of iodine. In a few seconds it darkens the image and produces an olive tint which possesses great printing intensity. Cars must be taken to stop the action before a yellow tint is acquired, which is less intense. Rinse with alcohol and dry before a fire.

GUSTAVE MACAIRE.—Many thanks for the excellent specimens and the interesting details in regard to them. The post office order has been received, and the BAY-BROOKS, &c., forwarded.

Several Correspondents in our next.

J. H.—Your enquiry how to make tracing paper for photographic purposes is scarcely sufficiently clear. We do not know of any photographic purpose to which tracing-paper is applied. Ordinary tracing-paper, which is chiefly used by architectural draughtsmen and surveyors for tracing plans, is made by saturating the paper with some kind of varnish, generally a mixture of turpentine and Canada balsam; but it may be purchased of most stationers better than it can be made by non-experts. It is probable you refer to paper for covering negatives to admit of easy retouching, and ordinary tracing-paper will scarcely be most suitable for such a purpose, as it will not be very easy to work upon its surface. Mr. Fry, the transparent paper best suited to that purpose may be obtained from Marion and Co., Soho Square.

PICTORIAL BACKGROUNDS AND HOW TO PRODUCE THEM.—Mr. W. E. Gower has issued in the form of a handy little pamphlet his instructions for the application of the powder process to the production of pictorial effects in portrait negatives; and illustrated his pamphlet with a capital illustration of what may be effected by the method. We are glad to possess explicit instructions in such a handy form.

SOMETHING LIKE PHOTOGRAPHY.—Mr. O. Cooke gives in the Society of Arts Journal an extract from a back volume of the Gentleman’s Magazine, which is curiously suggestive of a photogenic process. He says:—In the Gentleman’s Magazine, Vol. 88, p. 62, reference was made to a Prince de San Severo, at Naples, who had learned to give a fixed tint of any colour to white marble, so as to penetrate the mass, irrespective of any thickness, so that the figure of the Virgin, painted on a slab of white marble, was impressed on all the leaves sawn from the block. But, prior to 1800, an Englishman named Bird practised this art with success. Several specimens of marble thus coloured were shown to Charles II., and broken in the King’s presence, so as to prove such success. In the year 1745 the wife of a stonecutter named Long, at Bow, in Essex, also performed the art with success. At Oxford specimens of the coloured marble were also seen. The plan or recipe was to take two ounces of aquafortis and two ounces aqua regia, of sal ammoniac one ounce, and two drachmas of spirits of wine: also two drachmas of pure silver, with gold to the value of 4s. 6d., A.D. 1745. The silver having been calcined and placed in a vial the aquafortis was poured upon it. The silver having evaporated, a watery mixture was produced, yielding thus, then a black colour. Then the gold was calcined and placed in a vial, and the aqua regia having been poured upon it the mixture was placed aside to evaporate. The spirit of wine was then poured upon the sal ammoniac and allowed to evaporate. The result of these mixtures was a most remarkable. Those of our readers interested in photo-mechanical printing will find much that is interesting and instructive in this excellent monthly.

To Correspondents.

TALK IN THE STUDIO.

The meeting, which was very largely attended, concluded with a vote of thanks to each of the gentlemen who had contributed to the evening’s proceedings.

The space in any room which will admit of a wooden partition to make a dark room of four or five feet square. If so, that will undoubtedly be best, and might be easily and inexpensively managed.

JOHN STONE.—Some years ago we had considerable success in electrotype experiments, but not recently. We regret that we cannot help you in your difficulty, as we do not remember meeting with any similar case.

AMATEUR PHOTOGRAPHER.—Your examples of work are very good—the landscapes especially. The portraits are good, but the lighting is not quite satisfactory, that of the lady especially, in which the face is flat from the use of a direct front light. The greatest defect is the white sky in the unmoved landscape. The snow scenes are effective.

COMMEN.—Much depends on circumstances. The following are good proportions:—Length 28 feet, breadth 12 feet, height at eaves 6 feet, height at ridge 13 or 14 feet; north side and roof 3 feet opaque, south side and roof 2 feet 6 inches, and the remainder glass, to within 20 inches of the ground; south roof opaque, south side about 10 feet of glass. 2. The lens you mention may be used for cabinets; but if required for full-length figures it would need a small cabinet, and this would be in consequence of the smaller area on which to work the process, now a secret, will be sold for a price which will be duly published. We fear that the practice of photo-mechanical printing is too limited to induce dealers to keep any extensive stock of such materials, but there should be no difficulty in obtaining them when required.

R. B.—Plain prints may be produced on the unsigned side of albumenized paper; but so small a size as plain paper properly prepared. The paper should be floated on the ordinary silver bath with the albumenized side in contact with the solution. The toning and fixating may be conducted as usual. We have seen very good prints so prepared, and they are as useful in photographic purposes as any other of the usual method.

2. It is possible, by applying cuttlefish powder to the face of an albumenized print to secure a surface upon it to work with crayons.

M. K. L.—There are various modes of ascertaining the equivalent focus of a portrait lens. One of the most simple is that which we proposed many years ago. Take any flat object—say an engraving or diagram—copying or drawing on it, the image of the precise size of the original is obtained upon the ground glass. Now remove the lens and measure the distance from the ground glass to the object; one half of this distance will represent the equivalent focus of the lens.

G. M.—No report has yet been made.

J.—It is probable that the process of enamelling prints will tend towards permanence, and may be a great advantage to the image from atmospheric action. Waxing, and treating with the various emou paste will extend to protect the image.

PROVINCIAL PHOTOGRAPHER.—If our correspondent who used this signature a fortnight ago will communicate with Mr. R. Passmore, of Swindon, that gentleman will furnish him with some albumen plates which will suit his purpose.

B. E.—The best method of adding intensity to a varnished negative, in our experience, is that which we described many years ago. It consists in treating the negative with tincture of iodine, made by dissolving eight grains of iodine in an ounce of alcohol. First mounted the varnished with plain alcohol, and then apply the tincture of iodine. In a few seconds it darkens the image and produces an olive tint which possesses great printing intensity. Cars must be taken to stop the action before a yellow tint is acquired, which is less intense. Rinse with alcohol and dry before a fire.

GUSTAVE MACAIRE.—Many thanks for the excellent specimens and the interesting details in regard to them. The post office order has been received, and the BAIR-BROOKS, &c., forwarded. Several Correspondents in our next.
PHOTOGRAPHY IN AND OUT OF THE STUDIO.

In Memoriam.

The death of our old friend Oscar Gustav Rejlander leaves a gaping chasm in our midst, to be felt for many a year to come. His artistic productions were everywhere so well known and appreciated that his loss as an art photographer is great indeed. Those who denied that photographic works of art were bounded in their statement considerably when the charming productions of Rejlander were placed before them, for he was one of those who strove his hardest to prove the claims of art photography. If he was not successful from a worldly point of view, he certainly deserved to be; but he was too deeply wrapt up in the pursuit he loved so well to give much attention to aught else. It is surprising, too, how little credit he obtained from those outside the profession, for most people used to attribute his masterly sketches to good luck rather than to genius. “By Jove! what a pretty model that is!” was a remark often to be heard from people examining his fine studies; and it was only after a dozen pictures or so, all of them beautiful of their kind, had been inspected, that one began to think that perhaps something else besides good luck had to do with their production. How many times he made negatives before he was satisfied, and how long he had to wait sometimes before he could secure a model proper to his purpose, is known to most of his brethren. Rejlander used to compare photography and painting to steamers and sailing vessels, and would argue that the ship of the camera was more apt to reach its destination quickly to his destination and secure his result more rapidly than by the brush. Nevertheless, he said, the work was not done so quickly as some people believed, and study and thought were just as necessary with photography in carrying out any preconceived idea. Rejlander never pressed forward his claims to be a great photographer; he modestly allowed his works to speak for him. Indeed, his calm regard for everything but his art cost him much substantial loss, for his pictures were copied, and his ideas made use of by publishers and others, without permission or acknowledgment. How often have we not seen the pictures which he imagined and photographed, reproduced in illustrated periodicals? And yet it would surprise us to learn that Rejlander ever received a penny from this source. Only originals were sold, and paintings which had not been otherwise; but being only photographs, who would ever think of paying for them? Indeed the photographer should rather feel honoured in the matter, by seeing his works noticed. And so, perhaps, he might have done sometimes, had his name been attached to the pictures. Poor Rejlander’s works were admired and praised by all, by the ragged and penniless gathered round a window in the Street (where his works were generally to be seen); by the Heir Apparent to the Throne, who asked permission to carry home the artist’s own album, that he might have a better look at it; by his brother photographers, who crowded round his portfolio to see the latest efforts of their master. He had always something to show or something to explain, for he never held back experience or advice when he thought they would be salable. You must cut out just the middle— the bust, you know—and mount it on a card, and then it will sell for a shilling.” That was “usually the hope held out to him after making some great effort, and accomplishing something which secured the universal approbation. Fortunately O. G. R. he was familiarly called by his friends, cared little for worldly comforts, and he was too good a philosopher to be always grieving. He had done his best, he knew; he could do no more. He might have made money, no doubt, had he wished it, but it would have been at the sacrifice of what he conceived to be true art. He could not serve two masters, so he chose the latter, and lived as he best could with the little that fell to his providence, and careless of his means; and so he might have been, had the good-natured fellow possessed any wealth to squander. One of the last acts of his life will best illustrate his warm-hearted and kindly disposition. He desired much to help the Photographers’ Benevolent Association, but it was rather out of his power to do in the form of a donation; so he went home and made a selection of the charming studies we all of us know so well, and packed them up to be forwarded to the Secretary. He knew what it was to struggle through life, and his last desire was to aid others in making that struggle an easier one.

THE PRACTICAL PRINTER IN AMERICA.

XVII.—Continued.

There are other ways, however, to improve such a negative, and which are more or less dependent upon each other to produce the proper result. In place of shading the print after it is taken off the printing-frame, it can, if you choose, be done while printing, by shading the shadows of the negative with a cloth while the lights are printing. In the sunlight the cloth should always be in motion; in the shade, however, if the cloth is moved a little every minute or two, that will be sufficient. It is sometimes better to do the shading in this manner than in any other, when a bolder print is required than what would be obtained by shading it after it is taken from the frame. Sometimes when the shadows are very heavy, and get printed long before the lights get done, it will not then always answer our purpose to take the print off and shade it in the manner first described under the heading of this chapter, because it will often give a flat appearance, shade it as little as we choose, and instead of improving it, the contrary effect will be the result. This shows, then, that the lights need to be printed for awhile after the shadows are done, before we think of shading or tinting them by exposure to the light, and to tell when we have obtained the result we seek.

I will suppose we have a very intense negative, in which an attempt at shadow effects has been made, and violent contrasts have been produced. The subject is a lady who has gone too far away for another sitting, and the photographs are to be sent to her by mail, and as this is the only negative of her, it must be printed after it is re-touched, which latter process makes it still more intense. The printer here, then, has a difficult task to make a dozen prints from that negative, and upon making a proof of it, finds, as he expected, that the shadows are done a long time before the high-lights or lighter side of the face, and having removed the proof from the printing-frame when the shadow side of the face is done, he can then expose the lighted side for two or three seconds in the strong light of his lamp. After he has exposèd this lighted side, he takes it in, and immediately notices that the side is no longer white, but is decidedly flat, being all over alike from the top of the forehead down to the chin. There is then some detail wanted to be printed in on that side of the face, so as to prevent flatness, before we shade or tint the side by exposure to the sunlight. How can it be obtained?

There are several ways to do this, which we will here describe, showing the advantages and disadvantages of each. We might shade the shadow side of the face, by moving a cloth over the dark side of it while printing in
the direct rays of the sun, or by moving it once or twice every minute or two, if printed in diffused light.

Before proceeding further, I will here mention that we are supposed to be using the pink paper, silvered only a few seconds on a weak bath, fumed a few minutes, and then thoroughly dried.

In reference to the method last described, the results are always very satisfactory, while the disadvantages are many, viz.—1st. It is a tedious operation when the lighted side has to be printed considerably. 2nd. There is great danger of shading the background, drapery, &c., which will (especially when it takes so long a time to accomplish it) show badly, on account of the different depths of printing there is to them. 3rd. Every print you make will have to be printed with all of this trouble, and by the waste of much valuable time.

Our next object, then, is to obtain a better way to do this, which will have the advantage of being more easily and better done. There is a comparatively simple method, and we will try it. Instead of shading the shadow side when done, we will simply apply some transparent colour to the back of the negative, which will be done in such a way that while the lights are printing, the shadowed will print slower. By regulating the thickness of the colour on the back of the negative, we can make the shadows print about as we wish. Apply until you get it at the proper thickness or density, which is readily determined by printing a proof of it, with a single tissue-paper placed over the printing-board. This is to prevent the light from constricting the back of the negative, but it will print better, for this colour will more than counterbalance that which we may lose by the use of the tissue-paper.

When this colour is applied as it should be, you will then see that by the time the shadows are done, the lights will have enough detail in many places to warrant you to remove the print from the frame, and tint the lighted side as is described.

Upon looking now at the print, you will readily perceive at a glance that the side of the face of the lady's photograph is no longer flat, but there is a boldness, yet softness, to the whole. The detail which was printed in on the lighted side of the face was a little over the temple, and considerably more on the upper, middle, and lower parts of the face. This is what I mean by the back of the negative, and is just what was needed. Properly silvered pink paper, and a little judicious shading after printing, gave us a nice bold yet soft print, all detail, which we secured even in the deep shades, from a harsh negative, by proper masking or painting of the shadows.

Another way to print this negative would be to place it up against the window-glass, varnished side next to it, and lay a piece of tissue-paper on the back part of it, and with a lead-pencil mark on the paper just on the edges of the deep shadows which you wish to print slower. Now cut this paper out, and place it on the back of the negative exactly behind where the deep shadows are, and then place the negative out to print, after having placed another tissue-paper over the whole. In placing this paper on the back of the negative, raise the edges of it a trifle, so that it will not lay flat on the glass, and cause the edges of it to print.

Negatives which have either some transparent colour or tissue-paper placed on the back of them should always be placed, face up, to the strongest light, so that the places which are intended to be shaded will be so, for very often if you lay the board down flat the strongest light striking the negative causes the whole back of the glass, or the colour or paper to shade a different place than that which you intend it to do. This is especially the case when the place to be shaded is a small one.

The hands and arms, shadows under the eyebrows, shadows in the cheeks, shadows under the nose, the chin, the shaded ear, neck, &c., can very often be improved by either of the last two mentioned ways, viz., transparent colour or tissue-paper, sometimes one, and often the other, answering the better of the two. Do not carry either to excess, however, for the shadows need only to be softened more or less according to circumstances, and not entirely removed.

The transparent colour is really a good thing, as the following instance, of a very pretty lady that has come under my observation, will testify:—Miss Hattie W.'s negative is a "shadow" one, and she wants it printed in a vignette, but the lighted side does not, when the shadows are printed, possess sufficient detail unless we make use of this colour. As the prints from this negative are like the ones described last, we will have to blue-paint three-quarters of the whole face, which can very easily be done, and thus also get prints to be obtained from it, which, if we did not blue-paint it or fix in some way, we would have a very black shadow, which would greatly mar the beauty of the picture.

Sometimes two or three pieces of tissue-paper, cut to the size of the dark side of the face, and pasted (by touching the centre of each piece with a little starch) on the back of the negative, will answer the purpose.

An excellent way to print the negative, when it is to be printed either plain or in the medallion style, is to take a magnifying-glass—the so-called "sun-glass"—which has a diameter of about three inches, and by means of it to print up the intense parts of the negative, being careful, however, that you do not print the light to a focus on the negative for the you lose both the negative and print. We very frequently use the glass for the negatives, and also for printing detail in white dresses, &c.

For intense negatives, then, we can sum up the following remarks for their improvement in printing:—

1st. Pink paper should be silvered on a moderately weak bath, for a comparatively short time to what it is when prepared for weak negatives. 2nd. The paper should be silvered only a few minutes. 3rd. If printed as quickly as possible, which can be done by placing it in the strongest sunlight, with nothing over it, providing the quality of the glass, &c., permits. 4th. Soften the too deep shadows of the negative with some transparent colour, and thus permit the lights to print longer. Print such negatives under tissue-paper. 5th. Print until there is enough detail in the face to shoot the negative, but do not overprint. 6th. After removing the print from the board, soften the blanky whites of the face, light dresses, &c., by exposure to the light, protecting the rest of the print by some opaque paper, as has minutely been described above. 7th. Sometimes the whole print can be held out a few seconds with fine results. 8th. If the place to be tinted by exposure to the light are large, such as a side of the face, there will have to be some detail printed in on that side or place, as the case may be, before the print is removed from the printing-frame, so as to prevent flatness. 9th. By the use of a common magnifying or sun glass, the lights of the face, hands, &c., can be printed quickly and well. 10th. Study how to improve the prints in printing the order from a negative, and you will not fail to do something towards raising the standard of your work.

A FEW REMARKS ABOUT SILVER PRINTING.

BY J. BILSE, JUNE.*

I PROMISED this paper at our last meeting, not that I had anything new to communicate, but hoping that the little experience I have had might help these who only print occasionally, and so have time to forget how deep to print and how far to tone and fix.

Though the quality of negative is of the first importance to Trench a good print, it is not of much use discussing what that quality should be when the negative is varnished

*A communication to the Manchester Photographic Society.
and we have it to print and make the best prints possible. First, a few words about the paper: the double albumenised I have only used once, and do not intend to have any more. It gives very brilliant prints, warm tones, and is very liable to blustering, cracking, and fading. Ordinary Rives paper prints very brilliantly, and gives good tones easily, but is very liable to blister, and is not suited for printing from negatives printed in the skies—especially where the workers will know what I mean). I use it for weak, full-detail negatives and copies, but for regular printing from negatives with proper and too much contrast I prefer the thick Saxopaper, which seems to hold the fine light shades better during toning and fixing. I keep the paper flat and soft between two sheets of millboard in a bedroom which never has a fire in it.

The silver bath I use is forty grains to the ounce with nothing added, and though ten grains either way does not make much difference, I would rather have it weaker than stronger. I keep it clear by stirring it up with China clay every time it has been used; if this be neglected, the next paper floated on it will refuse to tone well, and make mealy prints. I have used everything known to clear the bath, but have found that two large jars, one large, and one large jar of water, by trouble as the kaolin, followed by settling and filtration, which I effect through a quart wine-bottle with the bottom knocked out, inverted, and the neck plugged with wet gun-cotton, which lasts indefinitely. In floating the paper I have a light at the other side of the dish, and by laying a near corner of the sheet down first I can see through this haze how low it is now; there are no bubbles, with which I am never troubled.

In summer I float the paper two minutes, draw it slowly from the solution and once over a long quarter-inch rod, hang it by a clip for ten or fifteen minutes, and dry off quickly and thoroughly by exposing the back of the paper to a fire. When all the paper is dry it is put in the cellar for five or ten minutes to damp, without which it would crack in the frame and print badly.

In winter the paper should be floated longer, as short floating makes brilliant prints, and long floating soft ones. A strong silver bath also makes brilliant, easy-to-tone prints, and a weak one softer prints, more inclined to meallness. The time between floating and drying has the same effect; for a paper dried too quickly is insensitive and prints brilliantly, while one dried spontaneously prints out. But if the light of the paper is not the reflection of metallic spots appear. In putting the paper in the frame care should be taken to dust the negative, and place any metal spot in the paper over a deep shadow; the pads and back are put on, but the springs not closed till all the frames are full. I use a pad of thick woollen cloth covered with paper saturated with a thirty-grain solution of soda carbonate, and dried. The weak negatives are printed in a weak light, either by covering with tissue-paper or placing them a long distance from the window. The good negatives are put where the best diffused light can get at them, and I have a few under-exposed ones which need the sun to make good prints, always remembering that by printing quickly a warm tone is easily obtained, and vice versa.

The judgment of depth of printing does not give me much trouble, though I make a good proportion of overdone prints through not being able to stay with the frames. I have seen it recommended to judge of the bronzing of the deep shades, but that merely indicates a strong silver bath. I judge principally by the lights and partly by the general appearance. The print should be about a third darker than it is to remain when finished, but this depends much on light, paper, and chemicals. I like to finish a lot of prints within two days from sensitising—not that the paper discoulours, but, if kept long, the metal spots seem to delight in the skies on one's most perfect pieces of paper, and this is the greatest objection to the otherwise successful methods of keeping sensitive paper white.

Suppose, now, we have a lot of prints to finish. Wash them in two dishes of water, and save it for the silver, and then wash ten or fifteen minutes in running water. I use the final washing trough for this purpose. The toning solution is the acetate bath of one grain of chloroid of gold in solution and thirty grains of acetate of soda in ten ounces of distilled water. The gold must not be very acid, and it should be added to the acetate solution at least a day before use; but if you have forgotten the gold until the prints are ready for toning, then boil the gold in a test-tube with a little powdered chalk and a few grains of acetate of soda, and add to the bath. My practice is to add to the above half-a-grain of chloroid of gold for every sheet of paper to be toned, and I make the addition when the paper is sensitised.

Now, having the untoned prints in a dish of water alongside the dish of toning solution, have a gas flame at the side of the toning dish farthest from you, and let the light be so shaded that it falls on the prints, but not on the eye, or you will soon have partial colour-blindness. The eye and flame should each be about eighteen inches from the centre of dish, and about two feet from one another. Now immerse the prints one by one, and do not have above six or seven prints to be toned at once, and large ones; for, as they begin to tone, and over a fresh light, or daylight it will look nearly as red as ever. Now put it back in the dish of water and agitate well, not with the fingers only, but with the flat of the hand, as if slapping something. I used to get very good tones by reddening the prints with salt water before toning, but it retarded that operation very much; I now get the same effect by salting after toning, but the tone must be carried a trifle deeper, as in this case they do not tone any more in the hypo, though it blackens the prints a little by dissolving out more or less of the red organic silver compound, according to the strength of hypo, and time of immersion in it. If the salt be not used after toning, the prints must be very thoroughly washed before fixing, for which I use three ounces of sodic hyposulphite to a pint water for every sheet of paper to be fixed. Two or three years since I used only two ounces to the print, and the prints have not shown the faintest trace of fading, discouluration, or imperfect fixation yet; but I use the stronger solution to save time. The prints are not allowed to rest in the hypo, but are lifted up, drained, and immersed one after the other, as quickly as possible. The time of immersion varies from ten minutes to not more than half an hour. If a print be dark in tone it is removed before those of a warmer tone, for the longer a print is fixed the blacker the tone will be. Fixing by artificial light makes the prints more permanent, and enables one to remove them from the bath before the tone gets too black after fixing.

I wash rapidly in three or four dishes of water, and after that for twelve hours in running water, for which I have a half-varnished, wooden trough one foot sixteen inches long, eleven wide, and three or four deep. One end is slanted, like the bow of a punt, and the water spreads itself by falling on this, moving the prints in such a manner that they somehow wriggle their tails, swim up to the water supply, and seldom go against the zinc grid at the bottom end of the dish, which is about half-an-inch lower than the inlets. Then I can wash them in ten minutes.

The contrivance of a contrivance. When sufficiently washed they are rinsed in a dish of filtered water, drawn over a glass rod, and put between clean calico cloths to dry. I do not believe in blotting-paper, as it cannot be washed.
Prints ought never to be mounted on white boards, as the light and delicate tones are not shown to such advantage as on a tinted mount. If a picture have not sufficient light in Herchel's comparison, it occurred to me that an instrument made to perform refraction mechanically would be useful in teaching optics, and that such a contrivance would only save pairs of wheels running on a table, into and out of a resisting medium. After a number of trials, made with the help of Mr. B. Knight, a simple arrangement has been completed, which answers satisfactorily in showing the behaviour of a ray of light under the various circumstances of ordinary refraction. Pieces of a thick piled velvety plush known as "imitation sealskin" are cut out to represent the sections of a thick plate, a prism, a convex and a concave lens, and glued on to smooth boards. The runner consists of a pair of boxwood wheels mounted loosely on a stout iron axle, and is trundled across the board, or, still better, the board itself is tilted up, and the runner let go in the proper starting direction. The following figures show the path of the wheels, always from right to left of the page.

In fig. 1 the runner starting from A enters the rectangle of velvet at B, where, its left wheel being first retarded, it shifts round into the direction B C, till it reaches C, where the left wheel first emerging gains on the right, so as to bring back the runner to the ultimate direction C D. This illustrates the refraction of a ray of light in entering and quitting parallel plane surfaces of a resisting medium, such as a plate of glass. When the runner enters at right angles to the boundary, its direction is, of course, unchanged, as with the ray of light.

Fig. 2 shows the path (ABCD) of the runner across a triangle, corresponding with the course of a ray traversing a prism. Also, by causing the runner to enter at about a right angle near E, a direction is given to it which, if the surface of the board and the triangle were similar as to resistance, would make it emerge near F, at a small angle to the side. But the left wheel passing on to the smooth surface gains so much on the right wheel, still in the velvet, that the axle sways round, the left wheel re-enters the velvet, and the runner goes off in the direction FG, thus illustrating the total reflection which takes place when a ray of light is directed to emerge very obliquely from a more into a less resisting medium, as from a glass prism, or a surface of water, into air.

The action of the double-convex lens in causing parallel or divergent rays to converge, is shown by the path of the runner in fig. 3, which requires no further explanation; nor does that corresponding to the divergent action of the double-concave lens (fig. 4). By starting two runners at once from the right-hand side of the board, so as to traverse the upper and lower parts of the convex lens, they are made to run into one another, thus illustrating the meeting of rays in a focus.

Lastly, by using two runners with wheels of different
diameters, as the refraction depends on the resistance to the wheels by the velvet, the apparatus may be so inclined as to show plainly their consequent difference of refractive

angles. The courses of the two are seen in fig. 5. This experiment, however, requires some nicety of arrangement.

Now the separation of rays of different refrangibilities by a prism being due to a like cause, this experiment serves to illustrate mechanically the decomposition of white light.

Let the large-wheeled runner represent the red ray, and the small-wheeled runner the violet ray, the principle of the prismatic spectrum becomes at once evident.

For the information of any who may wish to reproduce this simple apparatus, I may state the dimensions I have found convenient. The wheels may be 18 in. and 2 in., with rounded edges, mounted on a nearly half-inch iron axle, turned down to a 1 in. at the ends. The boards may be 2 ft. 6 in. by 1 ft. 6 in., with velvet on each side. It is convenient to place the velvet nearer to one end of the board to leave room at the other for starting the runner; and care must be taken to cut the velvet so as to present a good resisting surface, as this varies with the direction of the pile. In using the apparatus for teaching, care in manipulation is required to neutralise the defects of the texture. Some kinds of " Urechel velvet," to be had from the upholsterers, are more uniform than the " imitation seal-skin," and thus work more equally, but their effect is not so striking. Wet sand will answer equally well with the velvet, if metal wheels be used.

Recent Patents.

CHROMO-PHOTOGRAPHY.

BY WILLIAM M'GRAW.

The following specification of a method of producing various novel effects in photography was completed some time since, but its publication in our columns has been delayed:

"This invention relates to the production of chromo-photographs by the combined processes of printing, colouring, and transferring—in other words, to the making of pictures combining the fidelity of the photograph with the character, quality, and appearance of an artistic painting in oil colours, and that with the facilities of production of ordinary photography.

"In carrying out my invention I use ordinary negatives, but I do not use ordinary paper prints."

"The process is the following: I proceed in the first place to produce a print or copy from a negative that is independent of or that can be separated from the glass or paper or other temporary support necessary to its formation. For this purpose I coat one side of a glass plate with colloido-chloride of silver, having a good body of collodion, and having dried and fumed the plate with ammonia. I print strongly and tone the image, if necessary, with solutions of all or any of the chlorides of gold, platina, and sodium. With these three the operator, with a little practice, can produce a picture of almost any tone or colour, red, blue, or yellow, or combinations of them.

"To describe another suitable method:—I coat a plate of glass with plain collodion, and immerse in water for some minutes; I then pour over this wet surface a mixture of honey, albumen, and saturated solution of bichromate of potash in water, about equal parts of each, or I use other well-known substitutes, such as sugar-gum, and bichromate of ammonia. This prepared plate is dried at the fire in darkness, and after exposure to light under a positive photograph colour in powder is applied with a soft brush to develop the picture. It is now immersed in water, slightly acidulated with sulphuric acid, or a few drops of strong ammonia in the water serve the same purpose of clearing away the yellow chromate. This picture when dry is ready for the next process. For pictures of this kind a negative is required. I employ positive, or print from a negative obtained with colloido-chloride of silver, as already described.

"There are many other well-known methods or processes for producing prints suitable for this purpose, namely, the ordinary photographic collodion processes, wet or dry, as well as any improvements by the camera, the carbon process, the Woodbury process, or by any other method by which a photographic copy can be made that has the same or a similar appearance on either side when condensed upon glass. Having obtained the print on glass I proceed to the"}

"Painting.—I use the artist's oil colours mixed with Japan gold size, or other quick driers for saving time. I can also use water colours to begin with, as in the case of a portrait, for colouring the lips, articles of jewellery, or for thin white glazes, and so on. After that the picture is dried on glass, preparing the picture for the transfer. At this stage of the work some of my assistants prefer to apply the colour to the film photograph supported on paper and removed from the glass by pasting white paper on the film, using starch, sugar, or gelatine, or a mixture of these in water. This is allowed to dry, and can readily be removed from the glass. The work is then divided into small portions and applied to the glass again. This has the advantage, with others to be afterwards noted, of giving the picture in its true relative positions when finished in the case of direct prints on glass from negatives being used."

"Transferring.—The picture when dry is ready to be transferred to canvas, or any other suitable surface or material, and is, in fact, precisely in the condition of a picture ready to be lined, which is an ordinary operation of the picture liner. I smear the painted surface as well as the surface of the canvas with what is known to picture liners as lining paste (a mixture of glue and water). Then I spread the two together and press them together. The excess of paste is expelled by passing over it a smoothing iron heated to about 130°, and soon after the picture readily parts from the glass. It may be remarked that if the picture be removed from the glass while still wet and moist, a duller surface is got than when the picture is not detached for a day or two, when it then receives or partakes of the quality of the surface or its support, whether dull or polished. For the sake of cleanliness I have hitherto spoken only of painting the film as adhering to the glass; but in many cases it is the purpose of the artist to use the paper supported film for painting on, as in the case of transferring the picture to a rigid surface, such as a panel; and it becomes very important, when a number of copies of the same subject is required, as in the case of reproducing works of art, that the paper be so sized that the transference can then be affected by chromolithographic means, and when the picture has been trimmed at the edges and transferred with the painted side down, as already explained, to paper, cardboard, or other permanent support, the paper temporarily covering the picture is easily removed by passing over it a sponge dipped in warm water, or defects, as this can be dried at once. I then paint over the whole with the appropriate local colours of the parts, and the painting may be completed at once. It must be understood that the effect is to be observed from the other side, which can be readily done when the picture is placed on glass. After this painting is done I then place the picture upon glass, pasting white paper on the film, using starch, sugar, or gelatine, or a mixture of these in water. This is allowed to dry, and can readily be removed from the glass. The work is then divided into small portions and applied to the glass again. This has the advantage, with others to be afterwards noted, of giving the picture in its true relative positions when finished in the case of direct prints on glass from negatives being used."

"By another application of the same principle I can produce vitrified enamel chromo-photographs. In carrying out this part of my invention I produce a vitrifiable film photograph by either of the well-known methods known variously as Grazia's method or dusting-on process. I now cut from a large sheet of blown, thin, soft glass a piece of the required size and shape; I cover the convex side with this film, and site: filling up the concave with stucco, I subject this to heat in the muffle of an enameller's furnace. When cool, I paint this picture with appropriate enamel colours, and again fire. This thin glass, after the painted picture, is returned to the muffle picture side down, and allowed to fall over a white enamel surface prepared to receive it. The edges can now be grooved and polished to fit any setting."

"Having thus described the nature of my invention, and the manner of carrying the same into effect, I would observe that I do not confine myself to the precise details herein described, as they may be modified as circumstances may require; but what I claim as novel, and I desire to be secured to me by the hereinbefore in part recited Letters Patent is, the production of chromo-photographs by introducing colours between the photographic plate and its support, such photographs being embodied in a transferable transparant film or medium, the support being opaque."

ELECTION OF OFFICERS IN THE PHOTOGRAPHIC SOCIETY.

When during the American war the subject of the coming Presidential election was engaging public attention, Abraham Lincoln suggested the impolicy of unnecessary change in the executive during a time of such national disturbance, and gave point to his advice by relating an anecdote of the impolicy of "swapping horses while crossing a stream." The Photographic Society has been experiencing something of this impolicy. It has had occasion, unfortunately, to change some portion of its executive at the very time it was modifying its constitution, its laws, and its mode of action. The best of intentions and the greatest ability will not always compensate for lack of experience. The preparation of new regulations was proceeding with especial novelty, and neither precedent nor definite instructions existed as a precise guide. There are exceptional conditions that need special explanation, which is lacking. And in relation to those papers sent out, we have had many letters, some making complaint and protest, more a questioning for explanations. The voting papers are, unfortunately, scarcely sufficiently explanatory. The officers do not make it clear that a complete staff of officers require selection on the present occasion; and if the member refers to the law touching election of officers for guidance, he will find that, according to law, nine new officers only are required annually; namely, president, one vice-president, a treasurer, and six members of council. On this occasion, as all officers retire, all the places must be filled. All members are therefore at liberty to vote for eighteen members of council, a treasurer, three vice-presidents, and a president; but should they, from doubt or want of information as to the suitability of the candidates, prefer to vote for a few names only, such limitation will not in any degree invalidate the votes for those actually selected.

Another point of not less importance occurs in relation to the retiring officers, who, in the voting papers, are only given as retiring officers, without any intimation that they are eligible for re-election; and from this fact, and the mode of printing their names, it does not seem with any certainty to appear that they are really issued as candidates for office. The very fact that some of them are definitely nominated for election, whilst others are not, gives further colour to this supposed. It should be borne in mind, however, that the names of those unable to secure re-election to the offices they have individually held, without any personal nomination whatever, and all those printed as "reiring" are, in truth, printed so solely in order to place them as candidates for re-election.

Another form of complaint has reached us from several correspondents, but it is one upon which we can say but little here. It is complained that members who have not paid their subscriptions for the coming year, before the annual meeting will be deprived of the privileges of voting; and it is complained that, notwithstanding the intimation to that effect, in place of voting papers, have been sent to many members. As such a course appears to be in conformity with law, there is little to be said on the subject. One correspondent asks if it is ascertained that "every nominator has paid his subscription before he nominates, and if it will be ascertained that every officer, has, in like manner, met his obligations, to form a just argument to assume office." On these points the law says nothing. We can merely regret the questionable and offensive operation of a law which has been many years in existence, but which has not before, we believe, under similar circumstances, been applied, and, we may add, will probably not be applied again when once attention to its impolicy has been called. After the next annual meeting it is probable that the majority of the inconveniences and uncertainties caused by modification of law and usage will cease.

LICHTDRUCK PRINTING WITHOUT A PRESS.

Captain Delaunoy has published in the Bulletin du Jet in a report upon Jaubert's system, of photo-mechanical printing without the aid of a press. In the first place a carbon print is obtained upon a provisional support of glass or metal. This support is coated with a thin varnish, which facilitates the transfer of the prints subsequently; that recommended is a three per cent. solution of gum-dammar in benzole. The developed picture is allowed to dry, and a margin of wax is applied all round. A solution made up according to the undermentioned formula is prepared:—

- Gelatine .... 2 parts
- Gum arabic .... 1 part
- Glycerine .... 1
- Water .... 3 parts

The gum is dissolved first, and then the gelatine is added. When the latter has swollen sufficiently, the whole is warmed in a water bath, until completely dissolved. The solution is then filtered through damp muslin, and the glycerine added. This liquid is poured upon the carbon print of such thickness that the film, after it is set, is from four to five millimetres thick. So that the gelatine may spread the better, and shall not cool too quickly, the plate is warmed during the application of the solution. As soon as the film has become perfectly cool, it may be removed from the plate, but it is better to postpone the operation for four and twenty hours, for then it increases in solidity. The margin of wax is removed, and the film is carefully and gradually lifted off. The pigment picture remains in the gelatine film. If this print is now inked, an impression may be obtained by merely employing an India-rubber scraper.

Sometimes, on first applying the ink, the colouring matter remains adherent to the whole of the film. This does not matter much, however. It is only necessary to remove the colour with oil of turpentine, and then wash the film with a damp sponge, when it will be found, after rolling a second time, that the ink only adheres to the shadows. In inking up, either the ordinary lithographic roller may be used, or a glass tube ground on the surface. The roller is coated with ink by passing it over a gelatine plate once or twice, produced in the same way as above indicated, and coated with a mixture of two parts of printed ink with one part of oil of turpentine and varnish and a few drops of turpentine.

A few sheets of paper and an India-rubber scraper, such as is employed in carbon printing, is all the apparatus required for printing. You proceed as follows:—The gelatine film carrying the carbon print is placed upon an even surface. It is slightly moistened, and the excess of water
is removed with a wet sponge. Only the gelatine absorbs the moisture; the carbon print repels it, and takes up instead the fatty ink.

After the roller has been inked, it is passed over the picture until it has deposited sufficient ink. If the ink attaches itself over the whole surface of the film, it is a sign that prints, but not if half tones have to be reproduced. When the carbon picture has been well inked—a circumstance that is soon apparent after a little practice—a sheet of paper is put upon it, and rubbed two or three times over with the india-rubber scraper. The paper is then taken off the image, inked once more, and a second sheet of paper adjusted, when another print is secured. The printing goes on till the whole of the film becomes black. When a moist sponge is passed over, and the work may begin again.

You must not press too firmly on the film, else the picture will sink in, and no more colour can be applied; in this case the film must be allowed to stand for a few hours, and then work may be proceeded with once more.

The process gives very good results in the case of black and white prints, but not if half tones have to be reproduced. At the same time prints of the latter nature have been produced in this way, which give hope of an improvement in the process in this direction.

A great drawback to the process, if but the only one, is the difficulty of getting the lines straight, for the warm gelatine poured upon the pigment picture dissolves away the edges of the line and distorts them. We are in the hope of proposing in a little while some means of overcoming this defect in the process.

---

AN ALBUMENIZER'S LAMENT.

BY W. T. NOVET.

Albumenized paper! Thy name strikes not unpleasantly on the ear; thy smooth and polished surface assuredly deceives the eye if thou art sought but innocent. Yet manifold are the woes that, like foul fiends, lurk in thy spotless texture, and which, anon, will make men atemp with rage ere they consign thee to the flames as a worthless thing, a worker of hideousness and mystery. Nursed in all tenderness, handled with care, thou wert bathed in costly extracts, composed of the most precious metals. Well watched, thou hast basked in the sun, and on thy surface were printed, by an invisible agency, pictures of beauty and of beauty only, were viewed with feelings of hopefulness. Also! to be exchanged for despair when, from the final water bath thou percellum may emerge stricken with leprosy, covered with spots, a useless and somden deceiver, fitted only to perish by fire, or to be trampled under foot in a ditch! Say, then, ye initiated, "Why—wherefore—what can this mean?" Say: can it be that these evils have none other remedy besides fault-finding with the paper? Columns, counted in the aggregate, represent many volumes that have been written on the uses and abuses of albumenized paper. Perplexed photographers have in various ways received instruction, and have been recommended to try this now, this now—that, in all, no end of formula; whilst albumenizers have been lectured—often well scolded—and from them has been demanded that philosopher's stone, the secrets of salting, which presented, leave the consumers as wise as before. Most certainly the secret is theirs for the asking, but they can find no relief in their knowledge; and although this ado, this glowing and chaff, have grown stale by long usage, the fact needs no argument that we have entered upon another new year with indisputable evidence before us that the printing experience of the past has taught them the mistakes of the present, and the faults, repetitions of failure, blind reliance on formula, ignorance of principles, helplessness under trifling difficulties, the same eagerness to saddle with all sins of commission and omission the much abused, but frequently innocent, paper.

Having had the good fortune—or, in some respects, misfortune—to have written on printing matters somewhat considerably, I feel that I at least must have failed as a teacher, otherwise my pupils are dullards and unteachable, and the space I from time to time occupy in the pages of the News might have been more profitably employed in giving publicity to more valuable matters. Truly I have often noted in the teachings of others the same facts and phenomena which my pen pointed out and described years ago. I care not, however, to waste time in reclaiming discoveries, as I am one among those who believe that thoughts, like cart wheels, might accidentally move in one's way on a moist sponge, and the work may begin again.

Manufacturers of albumenized papers, although a suspected race, are not quite so bad as they are sometimes painted; and who can measure the task they are sometimes called upon to perform? They have a host of fastidious patrons to please, and if their attempts to accomplish this feat ever turned out successful, the victor would be only one removed from the Pope, and his Holiness you must know, is infallible! "Hap, rap." The postman has placed in my hands some half-a-dozen orders for paper. One asks for black tones, another purple and warm. The paper must be thick, must be thin, must in texture be fine, must be coarse, must give a vigorous print. Another must have sent him a paper capable of yielding a delicate image; "and pray do not forget to write out your very best formula." Last writer in theCorrespondeud columns of the News some time since protested against this anxious inquiry for instructions of the albumenizer. Blessings on so useful a friend. I fear, however, that his instructions, like my own, passed unnoticed; at all events, it is no unusual thing with me to receive applications for advice which would take at least two or three days to give all the details in writing. To present my case as I view it, in language candid and plain, I have no hesitation in asserting that whilst too much is demanded of the paper vendors, too little is known by printers of those principles on which depend that success which makes satisfactory the paper those vendors supply. Such being the plain truths attached to the case, I, purpose, with a view of giving the facts closer home, and in as few words as possible, expositing, pro bono publico, the secrets of an albumenizer.

First the raw material known as unprepared paper. Ah! in this matter our usually enterprising countrymen have permitted to slip through their fingers an opportunity of doing a well-paying trade. The German and French manufacturers have, however, the race to themselves, and of late the latter have been doing all the running. For several years the star of the house of Steinbach was in the ascendancy; but since the decease of the senior member of the firm bearing that name, the quality of the paper produced at their mills, both in colour and texture, has greatly deteriorated, and the Riex papers have now the superior demand, so far as the English choice is concerned; nor can this alteration in their taste be well wondered at if we consider how admirably the French makers have succeeded in improving their paper; and the quality improves with the growing demand.

For some time past the prices of the raw material have been moving upwards, whilst competition has driven the quotations for albumenized paper seriously down. That in itself is no pleasant xperience for the hard-pressed producer; but his troubles go further. The Germans having sent English photographers a favourite paper—favroured because of its extra bright glaze—the English albumenizers are thus placed between two walls: they must follow suit, or lose all their customers; hence, in lieu of the freshest of albumen, which once was their boast and their pride, they must perforce, ere they use it, allow their wbumen to ferment, to emit a foul odour, or the
required glazed surface lies beyond their best skill. For
know ye, O innocent photographers! that the brilliant
surface on your paper, although set down in the advertise-
ment as the product of albumen extracted from the freshest
of eggs, is derived from an albumen whose original fresh-
ness has been exchanged ere it was used! Then it was
stale. Fresh albumen, if rightly managed, is the article of
giving a fair glaze, and can yield a good body; but the
garish brilliancy now so often seen in photographic papers,
and so generally admired, cannot be produced with unfer-
mented albumen.

If the change of fashion just now alluded to entailed no
further evil than is engendered by the mere use of stale
albumen, probably no lessening of its employeability will
probably ensue. There are, however, difficulties in-
numerable which accompany its employment, a few of
which it might be profitable here to enumerate. "Tear-
drops," unequal absorption in the process of sensitizing,
followed by blotched prints; here all is right, there a lot of
round marks on the paper, with none but the faintest traces of an image
to be seen. Defects such as these arise from the use of a few
concentrated silver solution, which is "coated" in the first
albumen too quickly, giving no time for the silver to com-
bine with the chlorides within.

Next, I direct attention to the troubles of toning. Add
more gold to the bath, and then come the "measles." This
defect is occasioned by a absence of free nitrate, which
must be present, or the prints cannot satisfactorily be
made. To adjust this the albumen has an indifferent taste.
In the fixing bath, the paper, after the toning time, is
washed out in the first washing, and better washing. Less of preliminary washing. If that
will not cure, no washing at all. One of these causes, if
adopted, cannot fail of giving the conditions of toning
success.

Next the blisters, concerning which so much has been
written and said. To account for the cause of this evil I
have gone, and the albumen has an indifferent taste.
On the paper, whose surface has no interstices to act as
safety-valves when the pressure exerted by the contact
of fluids of different densities is brought into play. I have
observed that in prints on paper subject to blisters, if fixed
in a solution of moderate strength, and afterwards plunged
into a large bulk of water, the blisters form thickly, but
neatly, and when the prints are immersed in a few
pints of water. I can give no reason for this increase of
dimensions. I therefore state the circumstance as I have
found it.

In conclusion. My readers might safely accept this
description as their rule: the higher the glaze, if not fictitious—or, in other words, the product of rolling—the greater will be the difficulties to be encountered in working.
A paper to tone easily must be porous. A paper to print
rapidly must not be too salt. A paper that "keeps"
for days after sensitizing is in some way connected with
salt. A paper to give a good image must have a high
degree of contrast. A paper that gives brilliant tones
can only do so when toned up with judgment. Even then the
chief desideratum must be a suitable negative that can
produce a vigorous image. In short, the papers prepared
by most of our English albuminizers are capable of doing
all that reason can require of them; that is to say, if the
printer knows how to guide to success. The cuckoo cry,
"O! that admirable paper!" has really grown stale, and it
is high time that this note of excuse should be changed.
Given an evenly-albumenized paper, a clean surface, a
honest "talk," and the albumenizer has done all that lies
in his power to accomplish. Remember, his profit—once,
I admit, great—is now driven down to the lowest possible
mark. So I pray you, dear readers, cease to aggravate his
wrack by your over-indulgence in groundless complaints.

ENLARGED NEGATIVES FROM SMALL ONES,
WITHOUT A TRANSPARENCY, BY THE PLUM-
BAGO PROCESS.

By George Willis.

Since I wrote my method of working the powder process
which appeared in the News, November 20th, I have made
further experiments with exactly the same sensitive solution
as then stated, but in an entirely different direction. A
plate of the size of 24 by 18 inches was coated with the
sensitive solution, which I found could be as easily done as
with collodion, by using a long glass rod to assist the
solution to the edge of the plate. It was then dried, and
placed on a sheet of blotting-paper in a large clean box
in the dark, for thirty minutes; then dried by the fire.
A thin, good, detailed negative of the size of 4½ by 3½
was placed in the holder of the enlarging camera, which is a
darkened room which has a plank of wood three inches
thick planed smoothly, and with guides at the side, and a
clamping screw to fix the dark side in its place. This is
placed in a slanting direction pointed to the sky. After
the plate was got sharp on the ground glass, the plate was
placed in the dark slide, and an exposure of thirty minutes
was given. The plate was then placed face up on a sheet of
white paper, and a large soft camel-hair brush was used to
cover the plate with plumago. It was found to be too
soft and thin, which was the result of under-exposure.
Another plate was prepared in the same way, and exposed
for one hour, and the plumago was rubbed on as before.
After about fifteen minutes’ labour with the brush a good
negative was obtained.

Enlarged negatives from small ones, without any positive
interference, as in this case, seem to me to be superior to
all other methods of enlargement, so far as I can judge
from the little experience I have had at present. There is
one thing certain: that enlargements made in this way from
a good, small, well-detailed negative (rather thin) are
better modelled and more true in their proportions than ever
can be hoped for from large direct heads taken from
life, no matter how good the lens may be.

There is another thing: the enlarged negative may be
in its true position or reversed, at will; the only thing to be
done is to place the small negative which you please in
the camera, so that if a reversed negative is required, it
can be got without any transfer of the film, which is of
great advantage for some of the mechanical processes.
I have no doubt that in summer the exposure will be reduced
to about fifteen minutes. I shall experiment further in
this direction, as I have hopes that it will turn out to be
the best process for enlargements; and I hope shortly to be
able to lay before you both negatives and enlarged prints
done by this process.

FICHTERM'S ASPHALTE PHOTO-ZINCO-
GRAPHIC PROCESS.*

That a thin film of asphalté when exposed to the action of
the sun undergoes a change, and is afterwards less soluble
in its previous solvent, is a well-known fact upon which
many photographic processes are based. The sensitive
varnish is prepared by dissolving five parts of Syrian
asphalté in ninety parts of benzole, and adding ten parts
of lavender or spike oil, and filtering the same. A great
deal depends on the choice of the asphalté; those portions
only should be chosen which do not melt in a temperature of
90° Reaumur, and which are difficult to dissolve in
alcohol.
The benzole must be separated by distillation from
the more sensitive bodies it contains, and must be free
from water. The other oil must be quite pure, and also
free from water.

A perfectly clean and very smooth zinc plate is covered

* Correspondence.
Correspondence.

ELECTION OF OFFICERS OF THE PHOTOGRAPHIC SOCIETY.

Sirs,—You have been good enough to tell us recently the precise modus operandi of the new laws for electing officers of the Photographic Society of Great Britain. But the voting paper I have just received seems to be at variance with your instructions. You informed us that an entirely new council would be required. The instructions on the voting paper make no mention of the number of officers, and, on referring to the law which is quoted, I find six members of council, one president, and one vice-president are annually to be elected. In the absence of official instructions, I presume that the printed law is the proper guide. Again, you informed us that the retiring officers would be eligible for re-election. But in the printed balloting paper I have received, whilst the names of the officers are, as a matter of course, printed at the head of an official document, there is no intimation that they are candidates for re-election, or that any of them are eligible for re-election; they are simply described as the “retiring” officers, as in contradistinction to the candidates for re-election. Can you enlighten me as to the real state of the case?

Perplexity.

[All the retiring officers are eligible for re-election; and the election is for all officers. It is a pity that the balloting paper does leave the matter in some doubt.—Ed.]

Dear Sir,—I have just received an extraordinary circular from the Secretary of the Photographic Society, of which I am an old member. It informs me that in order to obtain the privilege of receiving a ballot paper, and the privilege of voting for officers for the coming year, I must first pay my subscription for that year. On reference to the laws I find that "no member shall have the privilege of voting on any occasion unless he shall have paid his subscription for the current year." As I have been for many years a member of the society, I have generally paid my subscription at the close of the annual meeting, and have never before been told that I must pay my subscription previous to voting at that or any other meeting. I presume this must be one of the new rules about which we have heard so much during the past year, and I must be allowed to remark that it seems to me most offensive and impolitic.

In addition to the law being offensive and impolitic, I should venture to assert that its application on the present occasion is illegal. When I joined the Society the annual meeting was, as it is now, in February, and the subscriptions were due in February. I think I remember that during the last year or two the accounts have been made up to the end of December; but I cannot see that my liability for payment is altered by such a stop. It seems probable that a large majority of the members will not have paid the subscription for the coming year before February, in which case they are practically disenfranchised; and the recent changes in law will limit instead of extending the voting powers of the members of the Society. Yours very truly,

An Old Member

[There is a clause in the laws to the effect quoted by our correspondent, and it is really a part of the old rules. As the law making the financial year of the Society terminate at the end of December was, so far as we remember, duly passed, every member would become amenable to the modified law, and the subscription would be due in January. Considering, however, that many members would scarcely be likely to have paid their subscriptions before the annual meeting, we should certainly doubt the policy of putting in force a penal clause under such circumstances.—Ed.]

REMUNERATION FOR NEW PROCESSES.

Dear Sir,—I have little doubt that some of your clever contributors will be able to perfect a plan from the following ideas. It is quite certain, in the present times of great competition, that no inventor of a new process can afford to give his time and experience for nothing, especially after the manner in which many kind gentlemen in this profession have been treated by Know-alls who knew all about it before, but were not generous enough to publish it if they did. We now miss the names of such masters in our art as Robinson, Col. Stuart Wortley, and many other practical men whom we provincials often had the chance of studying in print.

The new to the plan for investigating processes. Let two or three well-known men, from either the energetic South London or the Parent Society, form a committee of investigation. The inventor should enter his process on the books of the Society kept for the purpose, and at the time of entering should pay some fee. The process, if found perfect as stated by the inventor, should be granted a certificate stamped with the Society's seal. Then every purchaser of the process should pay a fee of five shillings for the seal of the Society, to be attached to every receipt issued, which would be a guarantee to the purchaser, and also form a fund for expense of investigation. This, I think, would be the means of keeping the vendors of old dishes re-cooked out of the market, and find many more purchasers for a really genuine article. I remain, dear sir, yours very truly,

H. Shatler,

Hedon, January 27th.

COMMITTEES UPON SECRET PROCESSES.

Sirs,—Will you permit me one or two words in reply to "W. E. B.," who seems strangely to misunderstand the aim of my former letter to which he refers. He says: "Photographers generally are willing to take and continue to receive freely. But what about the giving?" And so on.
He does not seem aware that he confounds two distinct things. When I quoted the passage, the meaning was surely clear to everyone, thus: freely ye have received information; freely give information. "W. E. B." seems to think it should be thus: freely ye have received information, freely give money! And because Archer, and Blair, and others freely gave the results of their study, process-mongers should, according to "W. E. B.", freely receive the money of the present generation of photographers. I will very readily admit that many photographers are not sufficiently grateful to the leading spirits who freely impart the results of their study for the good of the community; but the secret process-monger is too often one who has seized upon the results worked out and published by others, to sell for his own gain. Real novelties do not need to be sold as secrets in order to secure remuneration to their discoverers should remuneration be desired, as a real novelty can be patented, and, as a rule, when a process is sold as a secret, it is, if good not new, and if new unimportant. Nevertheless it may easily pay a busy man to buy such processes. The one point I have to urge is, that if committees are to be appointed they will do better service by reporting upon known but comparatively unpractised processes, than by reporting upon secret methods offered for sale. The remainder of "W. E. B."'s illogical letter I may safely leave with the note you attached to it.—Yours very truly, 

SHERZ.

CAUTION.

SrS,—Will you allow me to caution photographers against a person calling round to obtain silver cuttings, chloride of silver, &c., and who has a habit of taking such things away, promising to remit the value, and then not doing so. Lenses, cameras, and spare apparatus generally he obtains in the same way with the same result. Even when he buys and pays, the price given is far below the real value.—Respectfully, 

S. FAY.

DIFFUSED LIGHT AS AN ACCELERATOR.—THE "FLAPPER".

SrS,—So many enquiries have been made per letter and post card, that parties must excuse my not answering sooner, having to go away from home a few days up to London. However, I have answered many, and I think, for the benefit of those who wish to be raised by the first year's exhibition of life-sized photographs taken direct, and where no fear of display it created in the minds of all art-photographers who understand and have studied that branch of their profession, by first acquainting themselves with the optical laws which govern the working out of such problems. It was evident to all that no photographer of ability would ever attempt either to reproduce his sitters in that way, or presume to put before them results so obtained. To some, these statements may appear of a sweeping character, but I have good authority for going much further; after having entered my protest against the advisability or feasibility of taking life-sized photographs direct, I will show that even portraits obtained by enlargement cannot be without defects or distortions of every description, unless the small negative be so taken that the conditions of distance from the lens be fulfilled, and such lenses used as to warrant a perfect result. A few extracts, which I will translate from a learned French book bearing on this subject, will suffice to illustrate my statements, and show to what great extent care must be used to remain within the prescribed limits:—

"We will state at once that most of the portraits now exhibited are altogether distorted. The cause is a very simple one, and the use of short focus lenses explains the matter perfectly. If I wished to describe the defects which arise from this mistake I might write a whole volume, but the fact can be easily ascertained. Artists are not to be deceived on this point, although the general public may be. A little consideration will suffice to make the thing evident; look at most portraits, examine the features, particularly notice the nose and chin—both are protruding and en-
THE PHOTOGRAPHIC NEWS.

February 5, 1875.

To the photograph.

Largely to a surprising extent. Examine those large heads, and you will at once observe swollen faces in all of them. Some will say that this is an exaggerated description, but it is nothing more than absolute truth. The matter is easily explained, and to be traced solely to the use of imperfect or short focus lenses. By disregarding optical laws and the requirements of perspective, caricatures, instead of natural reproductions, are the results. Now what will be the consequence if you enlarge a negative which represents a very highly defected face? The same result. The drawing of an unpleasant incorrectness will naturally be the result, because all the defects will be proportionately magnified. While pointing out defects it is necessary to indicate the means of avoiding them; this is easily done—use medium or long focus lenses.

The limits of this letter do not allow of entering more fully into details, which, to most experienced photographers, can only be read in an article entitled "The Influence of Competition for Prize" in the Photographic News, November 27th, 1874, which shows conclusively, with regard to taking lifesize photographs direct, that the thing ought never to have been attempted, simply because photographers of ability have been engaged for over twenty years in the production of these pictures, and have never resorted to the direct process, referred to above.—"For so far as we know, life-size heads, produced direct in the camera, had never been attempted, certainly never exhibited before." Liverpool, November 30th, 1874. C. Ferranti.

Talk in the Studio.

Simple Combination Printing.—Mr. S. Fry informs us that, having tested Mr. Tilley’s mode of combination printing with much success and satisfaction, he has acquired the interest in it with a view to bring it out and place it in the hands of photographers on satisfactory terms. He believes it will be regarded as one of the profession generally.

Triumph of Venus.—Some negatives and transparencies of the recent transit of Venus, taken by Mr. Bruton at Cape Town, will be exhibited, by means of the spectroscope, by M. Frederick York, at the Photographic Society’s meeting on Tuesday evening next.

Photographing the Next Eclipse of the Sun.—Mr. A. Brothers, of Manchester, writes to the Daily News as follows:—

"Everyone interested in the subject will be glad to see that Mr. Proctor has called attention to a mistake which it is probable will be made in the method proposed for making use of photography during the eclipse of the sun in April next. If the attempt is to be made to photograph the image of the corona as seen in the spectroscope, no other result than failure may, I think, be looked for. The matter may be tested by any one having the proper apparatus, and the moon offers a favourable object. If an image of the full, or nearly full, moon can be obtained with a short exposure, then the brighter portions of the corona may give an image on the sensitive plate; but I anticipate that no trace of the less bright portions would be visible. The corona is so feeble an appendage of the sun. In 1871, with apparatus specially adapted, but similar to that used in 1870, the photographs confirmed the results of that year, and some extremely valuable pictures of the corona were obtained. The interest in the subject was by no means exhausted at this point, and now an eclipse is close at hand when a most favourable opportunity will offer for testing the power of the instrument in which the differences as compared with the pictures obtained in the years named above. With the apparatus used on former occasions only very small picture can be made. What is required now is a lens of such a size that it would give an image of the corona as large as the one we have yet seen. Lenses of the kind here indicated ought to be prepared for use when required, and no eclipse of the sun for many years to come ought to be allowed to pass (as was the last year) without some photographic record of it being attempted. If the Daguerreotype process could be used in addition to the ordinary method, it would be very advantageous; and if the stations were supplied with duplicate apparatus, one for short exposures, taking (say) ten pictures, and the other for long exposures, to take four or five pictures, some interesting and valuable results might be anticipated."

Removing Stains from Clothing.—Fresh ink and the soluble salts of iron—such as are used by photographers in their developing solutions, &c.—produce stains which, if allowed to dry, and especially if afterwards the material has been washed, are difficult to extract without injury to the ground. When fresh, such stains yield rapidly to a treatment with moistened cream of tartrate, aided by a little friction, if the material or colour is delicate. If the ground be white, oxalic acid, dissolved in the former concentration, will effectually remove fresh iron stains. Acids produce red stains, or blacks, blues, and violets, made from the vegetable colours (except indigo). If the acid has not been strong enough to destroy the material, and the stains be fresh, the colour may generally be restored by repeated soakings in dilute liquid ammonia, applied as locally as possible. Photographers frequently stain their clothes and cloths with nitrate of silver. The immediate and repeated application of a very weak solution of cyanide of potassium (accompanied by thorough rinsing to clean away water) will generally remove these stains without injury to the colour.—English Mechanics.

Action of Magnets on Spectra.—Some recent experiments described by M. Choquart to the Academy of Sciences recall the early experiments of Daguerreotypists, in which attempts were made to augment sensitiveness to light by connecting the plate with a galvanic battery. M. Choquart states that the effect of magnetic influence on the spectra of the flames of sulphur and selenium is to cause them to pale, and finally to become quite extinguished. On the other hand, the magnetic influence may be said to have the reverse effect, i.e., to make the spectra of chlorine and bromine more brilliant. The effect, says the investigator, is so rapid as to seem magical. The result of these discoveries is to render the deductions from the spectra of the heavenly bodies only to be accepted with great caution, and the views which have been virtually introduced must be considered in drawing conclusions from the aspect of the same.

Photography and Engraving.—A curious paragraph appears in the Paper and Printing Trades Journal, in which a novel charge is inferentially made against photography. Referring to the possibility of producing printing blocks with white letters on a black ground as desirable for display, and the difficulties hitherto experienced in producing such blocks, it proceeds as follows in relation to a specimen block it prints:—

"A cheap and effective method is required for producing casts from type with sunk letter and raised gentlemen. In this process, no matter how small, or complicated, will appear clear and sharp when worked. Many attempts have been made, and with varying success; but the results, so far as we know, have been expensive and uncertain. The block now shown was produced by the type being set, and pulled in a light blue ink; this impression was sent to a photographer, who made from it a glass negative, which gave white letters on a black ground. Messrs. Leitch then produced the block from an impression sent them. The result, as our readers will see, besides being exactly similar, is inseparable from the type. The result justifies the veracity of the report, and the photographer professes his inability to prepare a better." It cannot be doubted that this blurring referred to is not from any shortcoming of photography, but from the practice of using blue printing ink on a dark ground. Such a method could scarcely do other than produce a somewhat blurred, uneven impression.
METEOROLOGICAL REPORT FOR DECEMBER.
BY WILLIAM HENRY WATSON.

Observations taken at Braystones, near Whithorn, 38 feet above sea level.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

How to Bleach Shellac.—The Photographs of the Sun and Venus.—Chloride of Zinc and Gelatine.—A Tax on Photographs.

How to Bleach Shellac.—Those who employ bleached shellac in the preparation of their varnish often complain of its inferiority, for when in the form of a film upon the silver image it turns on a little yellow; because of this reason photographers generally content themselves with employing a light sample of shellac, which, however, not been bleached, preferring to put up with the inconvenience of the colour rather than run the risk of having a covering to its negatives which is not trustworthy. A plan for producing bleached shellac without in any way injuring its other properties has recently been given in the Hungarian Industrial Journal, and the subject is one that interests all photographers, we think the information may be useful to our readers. Ordinary shellac of good quality is dissolved in strong spirits of wine, and to the solution is added sufficient bone charcoal, in a finely powdered condition, to make a thin paste. This is put into a bottle of transparent glass, and placed in a warm place, and allowed to set for a few days, to shake up the mixture occasionally. Finally, the liquid is filtered, and the result is a solution of shellac which is of a very pale nature. We have no doubt that such a solution would be far better adapted to photographic purposes than one made from the bleached lac usually obtained in commerce.

The Photographs of the Sun and Venus.—We have seen some copies of the photographs taken on the occasion of the transit of Venus, and it is surprising how clearly the phenomenon appears on the plates. The pictures show a luminous disc of the sun about the size of an apple, the limb of the sun being in some of the pictures, far from sharp. Venus is seen like a tiny black corn in the middle of the white ground formed by the sun, now entering the sun’s limb, now progressing through the disc. The path can be accurately followed by examining a series of the photographs, and there should be little difficulty felt in making accurate measurements from the photographic results obtained. Some time must necessarily elapse before we receive the fruits of the investigations, for the calculations cannot be definitely concluded until the results from stations in different parts of the world have been received and inspected. It is said that the abstruse calculations necessary for the determination of the same position in the same general result, are undertaken by the Russians, who are looked forward to as being those from whom we may look first for an opinion. In the meantime it is matter for congratulation that our observers have been generally so successful in their efforts, and that the expenditure of so much labour and money has not been without a fair return.

Chloride of Zinc and Gelatine.—The use of chloride of zinc is being advocated in France just now for employment in collodion printing. It has been found that this substance is peculiarly fitted for addition to wet collodion in order to prevent its decomposition. Paper sized with gelatine to which a little chloride of zinc solution—say of six per cent. strength—has been added, possesses, moreover, the faculty of repelling moisture. The use of chloride of zinc with gelatine, employed as a collodion film, is also important, for if a printing block is immersed for a short time in the zinc liquid, the consistence of the gelatine is increased, and it becomes more solid, so that a larger number of prints may be pulled from its surface. The zinc, moreover, it is said, makes the gelatine surface more repellent of the ink, and the clogging of the plate with the black pigment is not so frequent as when gelatine alone is employed. If this is really the case, chloride of zinc will be an important assistance indeed to the photo-

mechanical printer, for the giving way of the printing block, and the adherence of ink over its surface, after the work has proceeded for some time, are two of the gravest difficulties that have to be contended with. Chloride of zinc thus employed would no doubt be a more innocuous clearing agent than acid, for the latter always acts injuriously on fine lines, unless very great care is exercised in the matter.

A Tax on Photographs.—The question of a tax on photographs has again been referred to, but we think there is little chance of such a measure being taken. A step of this kind would be as difficult to carry out as the tax upon matches, and would probably be quite unpopular. Only professional photographers could be taxed, for it would be impossible to charge for a very private portrait an amateur. This alone would lead to endless difficulties, for the question would be continually arising as to whether a picture was an amateur or professional production. Again, an amateur negative might be printed by a professional photographer, or vice versa, giving rise to endless difficulties. Another question would be as to the nature of the stamp, whether the same would be necessary upon a small as upon a large picture, upon a portrait as upon a landscape, and again a definition would have to be given to what constitutes a portrait and a landscape. We see the horizon so beset with clouds and fog, that any Chancellor of the Exchequer would need be a bold man who resolved to tax photographs. The utmost he could do, we should think, was to issue licences to professional photographers; but even such a measure as this would be most unsatisfactory and difficult to carry out.

FRENCH CORRESPONDENCE.

Permanent Photographic Prints.—Progress in Photochromy.—Removal of the Photographic Film from Glass.—A Simple Artificial Light.—Comparative Experiments with Different Sources of Illumination.

At the last meeting of the French Photographic Society, held on the 5th inst., a good deal transpired to bear out what I have already stated in previous letters about the progress recently made in the new methods of printing, both in carbon or greyink. M. Franck de Villeboille laid before the Society a numerous series of prints of various kinds, both upon paper and upon glass, by Mr. Johnson’s method; and Professor Stebbing presented a collection of stereoscopic pictures, and others, printed by M. Finlow, of Warwick. The latter productions proved that it was possible to print from four to five hundred impressions a day. All these are of the same general type, and fail to understand, and, as we have already stated, the Russians are looked forward to as being those from whom we may look first for an opinion. In the meantime it is matter for congratulation that our observers have been generally so successful in their efforts, and that the expenditure of so much labour and money has not been without a fair return.

M. Leon Vidal, who follows up his work with as much success as energy, sent me four impressions obtained by his new heliochromic process, for presentation to the Society. There was, first of all, a reproduction of a steam engine showing different metals; a mantelpiece in bronze, gilt, and enamel; and two bust portraits, carte size. The latter were obtained from which the impressions were taken were by M. Walery, of Marseilles.

The mantelpiece was the most remarkable of all, for the gilt was matt in certain places, and burnished in others; this appearance has been most accurately reproduced in the photochrome print. As the author remarks in his note, a mere examination of this specimen suffices to show the wide application that may be made of the process in the depiction of artistic objects alone. To any one who has but the slightest idea of painting or chromo-lithography, it is evident that it would be impossible to obtain a reproduction of the same kind, either by means of the brush or by lithography, without giving up much time to the matter; and at all events, it would be a most costly and laborious affair without the aid of the cameras.
Thanks to the photochrome process, it is possible, without being even painter or draughtsman, to obtain automatically veritable paintings exactly representing the model, and to pull them off in considerable numbers, the impressions being of an inexpensive character, carte-de-viste, for instance, costing but fifty centimes each. "At the present moment," says M. Vidalin his note, "the photochemical process has been brought to a point of per-fection sufficiently advanced to allow photography to include as one of its branches, and to permit of the widest and most unexpected applications.

A member of the Society made known at the meeting a very simple means of removing from the surface of glass the film of any cliché that may have been secured upon that basis. The method consists in rubbing the glass, before collodionizing it, by means of a tuft of cotton wool and some talc powder. The plate is then coated with collodion in the ordinary manner, and when the cliché has been taken, it may be gummed over, and yet removed with the greatest facility.

Another member remarked that the same method made use of before the preparation of plates by the Taupenot method (collodio-albumen process) preserves them effectually from any lifting of the film, which is sometimes experienced to the annoyance of the operator.

At the end of the meeting, MM. Riche et Bardy produced and exhibited to the members present a new light, of the most photogenic character, which seems likely to afford the most important services to the photographer. It was produced simply by directing a jet of oxygen upon a bit of burning sulphur.

I spoke recently of the binoxide of nitrogen and bish-phide of carbon lamp of MM. Delaichenel et Mermet. I said that it gave a very photogenic light, exceedingly regular in its character. Unfortunately, this lamp is founded on the employment of two gases whose combination gives rise to explosions, and, consequently, is looked upon with suspicion in photographic studios, especially as the gases eliminated are, moreover, of a most dangerous character. The illness, just now, of my friend Professor Stebbing, who has taken rather an active part in the experiments recently made on the subject, is a sad and striking illustration of this.

MM. Riche et Bardy have made an investigation of the matter, to discover whether it is the carbon or the sulphur from the bishphide of carbon which furnishes the photogenic ray. To solve the question, they compared, first of all, an experiment in which lights a bit of sulphur, and in order to render account of their action upon photographic preparations, they proceeded in the manner following. They prepared a glass plate prepared with pure bromide of silver by M. Stebbing, and cut it into strips two centimetres broad by ten long, and these strips they exposed one after the other under identical conditions to the influence of the various kinds of light they desired to examine. The experiments were all made the same evening; the sensitive plates were placed at a distance of fifty centimetres, from the source of light, and the exposure lasted sixty seconds, an interval registered by means of a chronometer.

The sensitive plates were enclosed in a slide under a screen furnished by ten sheets of waxed paper, superposed, two centimetres broad and of variable length. One measured ten centimetres, and, consequently, covered the entire length of the sensitive plate; the second measured nine centimetres, the third eight, and so on, until the tenth piece, which was but one centimetre long. These latter were pressed between a sheet of glass on one side, and a slice of horn on the other. The latter had marked upon it figures from one to ten, at equal distances, in such a way that the figure No. 1 was under the part corresponding to a single sheet, while the figure No. 10 was under that portion where the ten sheets of paper were superposed.

In this manner a screen was secured, the opacity of which was in proportion to the number of sheets superposed, which were indicated by numbers. For instance, if, after an experiment, it was found that the figures 1 and 2 were visible, and that, in another, the figures 1, 2, 3, 4, and 5 were seen, it might be concluded that the photogenic power in the second instance was stronger than in the first experiment, in the proportion of 5 and 2.

All the plates—prepared as dry plates, of course—were developed at one and the same time, and the table below shows the principal results obtained:—

Consequently, it is the light produced by the action of oxygen upon sulphur which, according to MM. Riche et Bardy, gives the greatest impression upon bromide of silver, and for this reason they do not hesitate to recom- mend its employment practically. It has besides other noteworthy advantages. It is not liable to explosion, and it is by no means costly, for there is but little apparatus necessary. An earthen vessel in which the sulphur is lighted, and a bag full of oxygen gas (which anybody may make for himself, or may purchase in commerce), are all that is necessary.

The surface of combustion may be augmented at will by employing for burning the sulphur a long vessel, so that several jets of gas may be directed from the bag upon the burning sulphur.

This artificial light, it must be admitted, possesses one drawback, like all others which deal with sulphides of carbon: a suffocating odour of sulphurous acid results from the light; but it is easy to get over this difficulty in a laboratory by placing the light under a chimney. The fumes are not very great in a spacious room; but in a small apartment they are unpleasant, and should be avoided. The most simple remedy consists in placing the vessel containing the sulphur under a large tube communicating with the chimney, in which a current of air is set up; or, better still, burning the sulphur in a glazed cupboard which is ventilated by a chimney shaft.

The experiments made by MM. Riche et Bardy before the French Photographic Society, with the assistance of Professor Stebbing, proved of the greatest interest to the members assembled. —Ernest Lacan.

ON THE VARIOUS STYLES IN PORTRAITURE.

By J. M. Turnbull.*

In the present short paper on the above subject, I will first set out by noting the various processes and phases of photography that have passed through. I do not, however, intend to dwell on them. Photography, for so young an art, has had many and various transitions, from the metal in the Daguerreotype to paper in the positive, and from that to paper in the negative process, to carbon tissue in the autotype, to greasy ink in the photo-lithographic and heliotype, till it will be difficult to tell where its various and final ramifications will end. Like other arts, it has

* Read before the Edinburgh Photographic Society.
also had its fashions and its follies. At one time the rage would be stereoscopic; at another microscopic; at another time enlargements would be the cry, at another some new dry process would absorb attention; while at another time photography would be chasing after some new and pantoys, much was to consider with respect to the art of photography, but which would in the course of a few months be quietly put to bed, never to lift its head again.

Photography may be divided into four parts: chemical, artistic, optical, and mechanical. It is natural, in an art like photography, that that part of it which first had birth (namely, the chemical) should first engage the attention of those professing it, and that until the conditions required of it in that direction were understood, little progress could be made with others. I need not here speak of the optical and mechanical, as they have kept pace with the chemical; when the chemical conditions called for mechanical arrangements, they were not found wanting. I do not overstep the mark when I say that the chemical and mechanical conditions required in photography are now so thoroughly understood that they may be considered as perfect. When I say this, I am very far from thinking we are at the limit of our chemical or optical developments. Indeed, I hope not—but what I mean to convey is, that the wet process, by which photography is ordinarily practised, is now so well understood, that I should not regard any man who is a professional photographer as worthy of the name who would make the condition of his chemicals an excuse for bad work. It is different, however, with the artistic division of the art, which has only of late years begun to attract the attention it deserves. It could not be expected of the early practitioners of the art that they could devote much of their attention to artistic matters, when they were groping their way with chemical difficulties and bad materials, sometimes brightened up by the appearance of one good picture out of a dozen bad ones, at other times in the depth of despair, from some calamity or other which was then beyond their knowledge.

In the Paris Exhibition of 1867 were exhibited some remarkable photographs; they were by a gentleman whose name has since become widely known: I refer to Adam-Salomon. The opinions regarding those pictures were very different. The opinion of some was to the effect that they were photographs untouched, while others maintained that a great deal of their effect was attained from retouching; while others were the length of way that they were not photographs, and that their whole effect was due to working-up. But all agreed as to their beauty, and that whatever their success was due to, they were pictures such as had never been before produced by photography. The practical effect of the exhibition of these pictures was to open the eyes of those interested in photography, more widely than ever they had been before, as to its capabilities, both artistic and manipulative. Their effect was to raise up many imitators of their style, and also to draw attention to the retouching of both the negative and print, to both of which the success of these pictures was no doubt partly due.

This retouching the negative has with some photographers assumed the form of a mania, so much so that every picture done by them, whether good or bad, had to be retouched, and this to such an extent that the photographic deficiencies were not only touched out, but others, done carelessly to the touching, were put in, till the final result was a silly waxified looking picture, the effect of which could not be considered due to photography. I do not deny that the result of retouching was sometimes what might be called pretty to look at, but when looking at any of these excessively retouched prints, it always puts me in mind of the following incident. When I was a child of nine or ten years of age (now a good many years since) I was taken to see a large travelling waxwork, by a near relative of my own. After having seen the whole collection, from Daniel in the lion’s den, and King Solomon in all his glory, to the last celebrated murderer—after having seen them to my heart’s content—the question was put to me, “But do you not see that they want something?” After having in my mind what it was that they wanted, I went over them not only properly but gorgeously dressed, that there was real hair on their heads, and colour in their cheeks, and that some of them were actually moving. I at length asked what it might be they wanted, and got for an answer, “They want life.” Now I never look at any excessively retouched (and may be beautiful) pictures, but the unwaxed waxwork, with the waxwork on it, while the waxwork in my mind, “They want life.” Certainly, if photography is capable of rendering a face with any degree of character or life in it, retouching, such as has been practised for years back, is just as capable of polishing it out again. It must not be thought, from what I have said, that I entirely condemn retouching. Photography has its defects as to colour, and it imperfectly renders some faces, as we all know. These defects I consider it quite legitimate to remove what I condemn is, the abuse or indiscriminate use of it, and the almost entire obliteration of all the delicate photographic detail. It is the practice of some photographers to sit for hours touching a single head, while all the touching that I would consider necessary would be to strengthen a little some of the lights, or make up any deficiencies in the shadows; it being more certain than any other way for the defects, all of which could be done in a few minutes. I am glad to see that a more healthy opinion regarding touching is beginning to spread among those who practise it most, and that those who formerly would not use it at all are now putting it to its legitimate use. I will wind up what I have to say on this point by a quotation from Sir James Reynolds:—"The thing in photography that I most abhor is the vain, unless at the same time there is preserved a breadth of light and shadow." Now retouching cannot put shadows in, though it takes them out; the most it can do in this direction being to bring up the lights, which is a very different thing from putting in shadows; in fact, its whole tendency is unnatural to flatten. My opinion of retouching, therefore, is, the less of it the better, as we all know, these defects I consider it quite legitimate to remove. One of the latest styles of portraiture I will now say a few words about. Though it is somewhat of a misnomer to call these pictures "Rembrandts" (at least, in so far as they bear any resemblance to portraits by Rembrandt), I do not object to the name, as they certainly bear a closer likeness to the style of Rembrandt than that of any other painter. But the pictures which pass current as Rembrandts in photography bear hardly little in common with pictures by that master. They want that beautiful luminous softness which is most apparent in Rembrandt's works, and I have never as yet seen any attempt in photographic Rembrandts to break up the black even background on which they are usually done. This is very different from the backgrounds in Rembrandt's pictures, which, though generally painted in a very low tone, are always full of gradation, softness, and contrast, which gives value and roundness to the figure. Listen while I give an extract from Fuseli:—"None ever like Rembrandt knew how to improve an accident into a beauty, or give importance to a trifle; if ever he had a master, he had no followers. Holland was not made to comprehend his power; the succeeding schools of art—cottage, cottage, the boor, the ale-pot, the shambles, and the haze of winter, with orient hues, or the glow of setting summer sun. No one combined with so much transcendant excellence so many in all other men unpardonable faults, and reconciled us to them. He possessed the full empire of light and shade, and all the tints that float between them; he tinged his pencil with all the hues in the cool of dawn, in the moonday ray, in the livid flash, in evanescent twilight, and rendered darkness visible."
Photographic portraiture in the so-called Rembrandt style has, however, been a valuable lesson to photographers; it has taught them that study more than ever they had previously done the various styles and effects in lighting, and the different ways and conditions under which a pleasing and satisfactory result could be arrived at. If Rembrandt photography had done nothing more than this, I hold that it will have done a great deal to advance photography. It is only by the careful study of lighting that the exponent of photographic portraiture can make any claims on, or make any real advance into, the domain of art. I do not, however, think that the Rembrandt style of lighting is the ultimate object which it should be the photographer’s highest ambition to achieve or master. I think it should only be a stepping-stone to lead us on in the study of lighting.

Of what I regard as the highest style in portraiture, examples are to be found in the works of Raimondi, Laurence, Gainsborough, Sir Henry Raeburn, Jackson, Northpole, and others. There is now on view at our Industrial Museum a collection of engravings from the South Kensington Museum, which is the finest collection of engraved portraits I have ever seen. They are nearly all splendidly executed by the same hand, and photography can have any claims on, or make any real advance into, the domain of art. I do not, however, think that the Rembrandt style of lighting is the ultimate object which it should be the photographer’s highest ambition to achieve or master. I think it should only be a stepping-stone to lead us on in the study of lighting.

A BATCH OF RECIPES.

We call from the pages of our excellent contemporary, the Scientific American, a batch of small recipes, all of which will probably be found of service at some time or other by photographers:—

1. Protosulphate of iron in powder, rubbed up with raw linseed oil, is an antidote for external poisoning by cyanide of potassium.

2. Rubber rings, slipped over bottles in packing, ensure safety against breakage.

3. Leather can be made hard by saturation in a solution of shellac in alcohol.

4. Paraffine is the best material for protecting polished steel or iron from rust.

5. Photographers who use large quantities of nitrate of silver should allow all the excess of silver, acetic acid, and other matters from the plates undergoing development to run into stone jars containing fragments of zinc. By that means the metallic silver may be collected. It should then be digested with dilute sulphuric acid, washed, and dried in an oven, so as to quite a large saving may result.

6. Lead nine parts, antimony two parts, and bismuth one part, is an alloy which expands on cooling, and which will be found useful in filling small defects in iron castings, &c.

7. Glycerine is an excellent coating for the interior of plaster moulds.

8. A strong solution of sulphate of magnesia gives a beautiful quality to whitewash.

9. Glass can be drilled with a tool moistened with dilute sulphuric acid. This last is better than turpentine.

10. White lead rubbed up with linseed oil to the consistence of paste is an excellent application for burn.

11. Gelatine mixed with glycerine is liquid while hot, but an elastic solid when cold. Useful for hermetically sealing bottles.

12. Black cement for bottle corks consists of pitch hardened by the addition of resin and brickdust.

13. Soap and water is the best material for cleaning jewellery.

14. Awnings may be made waterproof by plunging first in a solution containing twenty per cent. soap, and afterwards in another solution containing the same percentage of copper. Wash afterwards.

15. A handful of quicklime, mixed in four ounces of linseed oil, and boiled to a good thickness, makes, when spread on plates and hardened, a glue which can be used in the ordinary way, but which will resist fire.

16. A good walnut stain for wood is composed of water one quart, washing soda one and a-half ounces, Vandyke brown two and a-half ounces, bichromate of potash quarter of an ounce. Boil for ten minutes, and apply with a brush, either hot or cold.

17. A piece of alum as big as a nut will render clear a pale of muddy water. Dissolve the alum, stir, and allow the impurities to settle.

FURTHER OBSERVATIONS UPON SENSITIZERS.

BY PROPHOR H. VOGEL.

It has been settled beyond dispute that there are certain bodies which augment very considerably the sensitiveness of photographic plate, such, for instance, as nitrate of silver, nitrate of mercury, morrhine, pyrogallar acid, tannin, &c. Some time ago I proved that the property of these bodies rests partially on the tendency to combine with iodine, but is also dependent upon their absorption power of light rays. Among other things, I showed that pyrogallic acid may act sometimes as an accelerater of, and sometimes as retarding, the decomposition of light, according as it is employed one way or another, allowing the light to pass through, or become absorbed. Thus a solution of pyrogallic acid upon iodide of silver plates lessens the sensitiveness of the same, because it renders them more transparent; whereas if the covering of pyrogallic acid is allowed to dry, the sensitiveness of the plates is materially enhanced, because the transparency then disappears.

Now it is very remarkable that certain sensitizers upon bromide of silver act differently upon iodide and bromoiodide of silver. I first remarked this fact with morrhine. A solution of this material made up by dissolving one grannme of pure morrhine in 1,400 grannmes of water acts as a vigorous sensitizer upon bromo-iodide of silver; it enhances very materially even the same for green and yellow rays. As I have found in my spectrum of experiments. Upon bromide of silver there is nothing of such a sensitizing action to be observed. Neither in taking ordinary objects in the camera, nor in working with the spectrum, is an excited sensitiveness of bromide of silver to be found in the presence of morrhine, even in a dry state, but rather a decrease of the same, if anything. A similar negative result is given by pyrogallic acid upon bromide of silver.

This fact is not a solitary one. The same thing may be remarked with coloured sensitizers, such as fuchsin, for instance. This renders bromide of silver very sensitive to the action of yellow rays, so that with a long exposure the working of the yellow light exceeds that of the blue. Quite different is the action upon chloride of silver; in this case, in a short exposure, there is nothing to be observed of an increase of sensitiveness for the yellow rays; it is only after some time that the action becomes
apparent, and then in a less degree than in the bromide of silver.

It will be seen, therefore, that one cannot deduce from the action of an accelerative upon one silver salt the result upon another cafe.

An explanation of this abnormal behaviour should be sought for more in physical than in chemical influences. The plates are only affected radically by such rays as they absorb. The absorption depends, however, not alone upon the action of the colouring matter or sensitizer added, but upon their action in common with the chloride of silver or bromide of silver and the collodion. Perfectly neutral bodies may have an influence upon the matter. Fuchsin, dissolved in alcohol absorbs, for instance, only yellow and greenish-yellow, but dissolves in ether, or collodion, it absorbs the orange rays. For this reason it is that bromide of silver coloured with fuchsin is sensitive, not only to greenish-yellow rays, but also to orange. If chloride of silver shows this action in a lesser degree, it may be because that salt modifies the absorption properties of fuchsin. Further experiments in the matter are being undertaken.

So much, however, may be remarked in regard to the preparation of dry plates, viz., that it is an error to suppose that a preservative which works favourably for iodide of silver plates has the same action upon dry plates prepared with bromide of silver.

RecentPatents.

A REVOLVING CAMERA.

BY EDWARD ROGGIN.

The following specification describes a camera with revolving drum carrying a series of plates, in place of the ordinary dark slide. The patent was not completed.

"This invention relates to cameras for taking photographs in the studio or in the open country, and has for its objects to supersede the present form of cameras, with their cumbersome dark slides and focusing screens, which are continually getting out of order, and the intricate or complex arrangements of ordinary dry plate cameras; for getting the prepared plates into position without damaging the film thereon, or breaking the glass plate intended to receive or carry the negative picture; and to take or produce a number of pictures more rapidly and at less cost than by any other photographic apparatus hitherto used for the purpose.

"The means by which I propose to carry out the said objects of my present invention are as follows—: I construct a hollow drum, or the skeleton frame of a drum, or of a many-sided figure hereinafter called the 'drum,' of suitable materials and dimensions, in the top and bottom discs of which drum grooves are cut or formed therein for the insertion therein of any convenient number of prepared glass plates, either wet or dry, on which portraits or other pictures are to be photographed. The skeleton frame may also be formed with any number of sides, according to the size and number of the plates desired to be placed therein, leaving a narrow slit or opening behind or opposite to a fixed plate of ground glass, called the 'focusing glass,' to focus through. The angle pieces of the said skeleton frame are properly grooved to receive and hold the prepared glass plates. These arrangements being made, so as to form a figure with regular and equal sides, or nearly so, in order that each prepared glass plate may, in succession, be brought, by the motion or turning of the drum, into the exact position previously occupied by the focusing glass, this drum is then inserted in a box or case, and is so pivoted therein that it can be freely revolved or turned by a handle or框架协议 on the upper portion of the skeleton frame. The box is provided in front with a sliding lens, and behind, and directly opposite the said lens, with a small strip or plate of yellow or other suitably coloured glass to focus through, and to protect the prepared plates from the effects of the light thereon when revolving the drum.

"Securely fixed on the top or lid of the box, and centred on the said upper pivot of the drum, in a circular drum plate, and near to the circumference of which, at the proper distance from, and corresponding with the number of plates or sides of the drum, the ground or focussing glass plate being fixed in, and forming one side of the drum, is always in its place, and cannot be easily damaged or destroyed; this focussing glass I denominate Number 1, and the prepared glass plate next thereto—say on the left hand—Number 2, and so on with the remainder of the plates in the drum, following in the same direction.

"In operating my improved camera, I turn or revolve, or partially revolve, the drum, which has been previously supplied with prepared glass plates, so that the figure points to or is over Number 1 on the drum plate, when the focussing glass is in position behind the lens, and directly opposite the coloured glass in the box, and the narrow opening in the drum, on looking through which coloured glass and opening so placed in line the picture is seen on the ground glass, and the apparatus is ready for focussing. When the focussing is completed, I close the slide behind the lens, and move the finger to Number 2 on the drum plate, which prepared glass plate is in position, behind this glass plate occupied by the focussing glass, when it is ready to receive the image or picture, as previously seen on the focussing glass. In this way the whole of the prepared glass plates in the drum are, in succession, brought before the lens, and receive an impression or picture.

"When different views are required on each of the plates in the drum, after taking the first view as previously described, the finger and ratchet wheel are again turned round to or over Number 1 on the drum plate, when the focussing glass is again behind the lens, and the apparatus ready for view; when this is arranged, the drum is turned until the figure points to Number 3 on the drum plate, so as to present another prepared plate behind the lens, and the second view is taken, and so on for the remainder of the said prepared plates in the drum, the sections of the drum serving the place of dark slides at present used.

"My apparatus may be made in different forms, the main or leading features being retained in each case. For example, for a camera for the studio, where only one or two plates are required at one time, the 'drum' may be only a quadrant, or one-fourth of a circle or polygon, wherein the plate or plates died material which will not warp or be otherwise injuriously affected by variations of climate. It may also be made of paper for a toy camera, with a bull's-eye lens to exhibit small transparencies. Its construction being exceedingly simple, it cannot easily get out of order. It is very portable, and can be at any time put together, or disassembled, where the drum revolves on a vertical axis or on pivots.

"My improved revolving camera is especially adapted for taking small views to be afterwards enlarged, and for taking 'negatives' for producing transparencies for the magic lantern; also for taking views in streets, and of processions, and the like, as from thirty to forty views can be taken in a few minutes.

"The camera may be of any size or dimensions, and can be produced at less than the present cost of similar articles, and be more durable. It may be made of wood, tin, brass, or other suitable material which will not warp or be otherwise injuriously affected by variations of climate. It may also be made of paper for a toy camera, with a bull's-eye lens to exhibit small transparencies. Its construction being exceedingly simple, it cannot easily get out of order. It is very portable, and can be at any time put together, or disassembled, where the drum revolves on a vertical axis or on pivots.

Photographic Use of Platinum and Indium.—Salts of these metals are, according to Mr. Willis, in the Polytechnisches Notizblatt, sensitive to light. If paper be fixed ready to receive a solution of platinum chloride and plated with platinum chloridum, then dipped into a solution of nitrate of lead, dried a second time, and finally washed over with an acid solution of oxalate of iron, a sensitive surface results, on which images may be printed under a negative. They require development with a hot solution of oxalate of potash, which brings them out of a rich black colour.

White Enamelled Plates as a Substitute for Opal Glass

A novelty which possesses much promise has just been
introduced in the United States. It consists of a ferro-
type plate with a perfectly white enamelled surface,
intended to take the place of porcelain or opal glass as a
basis for a collodion-chloride of silver prints. The American
journals speak in high terms of the results as very
promising, and the great advantages over glass scarcely require
enumerating to be appreciated by photographers. The
plates are thin, light, not fragile like glass, easily cut like
paper; unlike glass, they are not rigid, and are therefore
less likely to injure the negative in printing; and they
will doubtless be less costly than glass. The surface is
said to be very delicate, and of a pure white. There is
one point in which it is probable they will scarcely equal
pictures on porcelain in beauty. The surface will necessi-
tarily be opaque, and hence the peculiar diaphanous effect,
which is an especial charm in the photograph on opal
glass or porcelain, due to the semi-transparency of the
material, must necessarily be wanting.

But there is another point of considerable importance
upon which we feel bound to suggest a caution. Our
American contemporaries speak of the prints as of
undoubted durability; and the assumption, in the absence
of experience, is a fairly legitimate one. But, although the
Nonpareil plate, as it is termed, is a novelty, we have
sufficient experience to interpose a doubt. About ten
years ago, soon after we had perfected the collodion-chloride
process sufficiently to justify us in giving it to the public,
we sought about for various substances with fine white
surface upon which the prints might be produced, the
sensitive collodion-chloride emulsion lending itself to a
variety of novel forms of printing. One of the first things
which occurred to us as suitable was the ferrotype plate,
it being made with a white enamelled surface in place
of a black one. As this experiment was not easy to try,
we thought of another substance somewhat analogous: we
obtained some tablets of paper made with a white
enamelled surface, which would be produced, we apprehended,
in a manner very similar to the white enamelled surface on
a ferrotype plate. The results were in many respects very
sharply contrasted, but there were one or two drawbacks. We
found, on more than one occasion, that the whites of the
finished picture darkened somewhat in sunshine and
further experience suggested a cause: we found, in some
cases, when we cleaned off the film in case of an unsatis-
factory print, that a faint image had been formed on the
enamelled surface itself beneath the film of collodion.

The albumen and beer process, and the recent transit of
Venus

This showed that an actual combination had been formed
between the free nitrate present and the white enamelled
surface. Whether this combination were formed with the
resinous substance in the varnish which forms part of the
enamel surface, or with the white pigment mixed with it,
we cannot say: but a combination which darkened under
the action of light, and which was not easily removed by
the action of the fixing salt, was clearly formed, and such
a combination is clearly iminal to permanency. Another
incidental difficulty once occurred. The ether and alcohol
in the collodion chloride, and the heat of direct sun printing,
on one occasion sufficiently softened the surface to produce
adhesion, and we found tablet and negative in such perfect
contact that they were not separated without the destruc-
tion of both. This latter misfortune—possibly the former
also—was probably due to the enamelled surface being
less perfectly finished in the few tablets which were pre-
pared expressly for our experiments than they would have
been in ordinary cases, and, perhaps, slightly greater risk may
be found in the Nonpareil plates; but the possibility
should be noted, and so serious disappointment possibly
avoided. We hope that our caution will prove needless
with the new plates.

Toughened Glass for Negatives

A discovery has recently been made in France, which,
if it should prove equal to its promise, will be found a
boon of great value to photographers. There is no
mistake in photography, perhaps, more mortifying
than the breakage of a fine negative in the midst of
demand for prints, and it is an accident that, in spite
of the greatest care, will occasionally happen. A discovery
whereby the fragility of glass could be entirely
removed would be one of the most valuable contributions
to science which can be conceived, and it is at least a step
in this direction which has just been secured: a means of
making glass comparatively tough without destroying its
transparency has been discovered. We give the details
just as we find them in the Times of a recent date:

"It has long been known that when glass is heated to
redness, and kept at that temperature for a considerable
time, it acquires properties of porcelain in a round
manner. Thus it becomes opaque or feebly translucent,
much harder and tougher, and somewhat like porcelain
in appearance. This change is termed 'devitrification,' and
is caused by the conversion of the glass into a confusedly-
crystalline mass, of which sections are beautiful objects
when seen with a microscope in polarized light. The
subject was investigated by the renowned French philoso-
fopher, Réaumur, early in the last century; and to objects
of devitrified glass the name of Réaumur's porcelain is
usually applied. Such objects are exhibited in the
Museum of Practical Geology in Jermyn Street. It has
been reserved for another Frenchman, a gentleman
farmer, to discover the singular fact that when glass is
heated to redness and then cooled or annealed on its
surface toughness is greatly increased, or, what is equivalent, its
fragility is greatly diminished, while its transparency
remains the same. Thus, suppose a rectangular pane of
glass placed flatwise and supported on two of its opposite
edges to break when a given weight is allowed to fall upon it
—say from the height of two feet—it would, after
having been toughened in the manner above stated, resist
the same weight falling upon it from the height of six
feet or eight feet. It is strange that, although glass has been
manufactured during the last two thousand years, yet such
a simple and probably very important fact as this should
only recently have been found out, and equally strange
that the discoverer should be a gentleman farmer. The
foregoing information on the new process of toughening
glass is given on the authority of Dr. W. Siemens,
F.R.S., well known in connection with telegraphy,
and the furnace which bears his name. His brother,
an eminent glass-maker at Dresden, has tried the process,
and pronounces it to be 'certain and unquestionable'."

METHYLATED ALCOHOL IN PHOTOGRAPHIC
MANIPULATIONS.

At a recent meeting of the French Photographic Society,
M. G. Noel, an amateur, called attention to the advantages
that may be derived from the employment of methylated
alcohol, or wood spirit, in the operations of developing
and intensifying the image. The cost of methylated spirit
is, of course, much less than that of the pure alcohol, being
only about a fifth of the price, but this is not the main
point. M. Noel states that by using wood spirit in his
developer he is able to reduce the exposure of the plate in
the camera very considerably—from fifty-eight seconds to
eight, or even six, he tells us.

M. Noel's formula for preparing his developer with
methylated spirit is the following:—

<table>
<thead>
<tr>
<th>Substance</th>
<th>Grammes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Water</td>
<td>...</td>
</tr>
<tr>
<td>Ammonisal sulphate of iron</td>
<td>16</td>
</tr>
<tr>
<td>Glacial acetic acid</td>
<td>... 8</td>
</tr>
<tr>
<td>Methylated spirit</td>
<td>... 15</td>
</tr>
</tbody>
</table>

He affirms that a developer thus composed may be used
with confidence with very short exposures, and afford
results quite equal to those given by an ordinary developer
with a prolonged pose. In compounding his intensifier
M. Noel also uses methylated spirit, making up his solu-
tion as under:—

<table>
<thead>
<tr>
<th>Substance</th>
<th>Grammes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Water</td>
<td>...</td>
</tr>
<tr>
<td>Pyrogallic acid</td>
<td>... 200</td>
</tr>
<tr>
<td>Citric acid</td>
<td>... 60</td>
</tr>
<tr>
<td>Methylated spirit</td>
<td>... 10</td>
</tr>
</tbody>
</table>

M. Noel has such confidence in both these solutions,
that he has ceased to employ any other in his photographic
work.

CORRESPONDENCE.

RE "SENEX," THE EDITOR, AND SECRET
PROCESSES.

Sir,—I trust you will permit me a few words in reply
to "Senex" and yourself. "Senex" is perfectly right
when he says of me that I am not aware I "confound two
different things." When "Senex" reflects upon what the
wealth of a nation consists of, he will see that information
forms no inconsiderable portion, while money is not wealth,
but simply the measure thereof; thus information and
money are not so wide apart as he appears to place them.

However, let us take his new way of putting it—the way
I was so stupid as not to see: "Freely ye have received
information, freely give information." Well, how about
those who have no information to give? In this case you
would have men who are capable of original advancement,
freely giving and receiving information from those of equal
capacity; in short, it would be simply an exchange, and
the noble army of incapables receiving, and giving nothing
in exchange. Truly this is an equitable arrangement!

However Iobese I may be, I certainly never argued that
because "Archer, &c., gave freely, process-mongers should
receive money from the present generation of photographers."
This is such a novel idea that I consider it worthy, and
intend to insert this original bit of "Senex" in the
exercises given in the Appendix to Whatley's Logic.
However, I would say to those who may have valuable
information, and the result of their own investigation, to
reflect upon the magnificent rewards given to such men as
Archer, &c., before taking the advice of Mr. W. E. B.

And now for the "remaining of W. E. B.'s illogical
letter." In Blair's amount I was in error; my file of News
being at my house some eighty miles away, I could not refer,
and spoke from memory: this you will excuse. In Archer's
case I was right: compare £747 with the £1,000 asked for
an enamelling process (the annuity of £50 is the bounty of
the nation, and not the profession); compare Goddard's
works with £500, asked for the formula of an intensifying
paper. These instances show what value commercial men
place upon small work. By a similarity of reasoning, what
would be the value of the works of Archer, Blair, and
Goddard? In the main I was right when I said a couple of
thousand pounds would cover all that the fraternity has ever
given to these early pioneers. And now let photographers
lay their hands on their hearts and say they have done to
those men as they would have others do to themselves.
Why, Mr. Editor, if you were to die, poor photography
would let the workhouse officials dispose of your remains.

I still think the schoolmaster argument sound; but there
is a peculiar ambiguity in the word "new." There is a
sense in which the instruction of the teacher is new, and
there is a sense in which it is not. Which of these
meanings are we to use? That is, if we are further to discuss
the matter by my undertaking to show that the teacher and
so-called process-mongers are alike.

As you appear to misapprehend me, I may say, once for
all, I do not pretend to defend, nor have I any sympathy
with, any process-dealer who makes false representations.

Yours, &c.,

W. E. B.
Halifax, February 6th.
SELLING AND GIVING IMPROVEMENTS IN PHOTOGRAPHY.

Sirs.—There is an error entertained by many, in connection with the history of photography, which has been so often repeated that it is now somewhat regarded as a fact. It is so definitely stated in the otherwise able letter signed "Sene," in your issue of the 28th ultimo, that I am tempted to offer a correction. "Sene" states what has often been stated before—namely, that almost every great discovery and great improvement in photography has been given freely to the public. This, I venture to say, is a very decided error, and although the statement is ungracious and unkind, it is recounted in proof of my assertion. It is a fact that almost every great discovery and improvement in photography has been protected by patent, instead of having been given to the public. Let us look to the record.

Daguerre, who received a handsome pension from the French Government in consideration of giving his discovery freely to the whole world, notwithstanding this secured a patent in this country.

Fox Talbot patented his Calotype process, as well as a number of less important improvements.

To Scott Archer there is little doubt the credit of discovery of the collodion process belongs; but the fact that the process grew out of an attempt to improve the surface of paper with collodion, all the steps of which were familiarly known to many persons, and the fact that prior suggestions and experiments with collodion had been made, prevented the completed discovery from being patentable; but Mr. Archer patented immediately after the smaller thing, to which his claim was safe—namely, the use of gutta-percha for transfixing the negative film.

Poiernin, Fargier, Swan, and Johnson, all patented their great discoveries in connection with carbon printing, and a number of others patented minor and less important matters connected with carbon processes.

Woodbury patented the process connected with his name, and has also patented a number of minor inventions and improvements.

The number of patents taken out for real or supposed photographic improvements is very large indeed, extending, I believe, to some thousands; some for real discoveries or inventions, some for valuable improvements, and a still greater number for things which were old, unimportant, or worthless. In all cases the labourer is worthy of his hire, and of remuneration when a really good thing protected by patent, as, besides giving the real inventor a chance of remuneration, it also affords the public the guarantee of excellence which is only secured by some one person having an interest in making the best of the process; whereas it often happens, when a thing is given to the public, it is like a piece of public land: as everybody may cultivate it, no one person does so. A patent for a good thing is a public benefit, whilst a secret is a public evil.

Nevertheless, whilst I deny that the majority of great discoveries and improvements have been given freely to the public, I do not deny that a spirit of genuine liberality has prevailed amongst photographers as to points of improvement in practice, and sometimes even in relation to discovery. I may mention the collodio-chloride process, given by the Editor himself; the collodio-bromide process, by Messrs. Sayce and Bolton; the great improvements in that process by Col. Wortley and others; the alkaline development process, which, if not invented by Major Russell, was well worked out by him, and freely given; a score of points of improvements in practice of such men as Robinson, Blanchard, Abney, Bovey, Fry, Crompton, and others, of which I might almost take the index of the Year-Book of Photographic News for the last few years as a muster-roll. If every minor improvement made by such men were preserved as a secret, and sold at a price, a revolution would be effected in the spirit and relations of photographers of a very undesirable sort. It is to the minor improvements freely made known in societies and journals that so much real progress is due. Great discoveries and great improvements can be, as they have a right to be, easily protected by patent; but it is a bad sign of the times when small improvements, insufficiently novel or insufficiently important for protection by patent, become the subject of petty buxtering. If, however, such things may, in some cases, be with propriety tolerated, at least let photographers avoid dignifying the practice by appointing committees to report upon their claims. Buying a secret must always resemble making a venture in a lottery; let those who are prepared to stake the amount, take all the risk without grumbling; and remember that whilst it is a pleasant fact to contemplate that many photographers have been very liberal in aiding their brethren, that fact does not give photographers generally a vestige of claim to be taught everything for nothing.—Very truly yours,

Y.

RENOVATING THE NITRATE BATH.

Sirs.—I cannot agree with Mr. El. Shaylor that it is the province of societies to investigate and report upon processes offered for sale. Indeed it is the aim, and very properly so, to avoid all connection with the commercial side of photography. But some years ago the South London Society appointed experimental committees, and I remember that some very useful information was contained in their reports and the members were not compelled to do more than to report on questions of the day? For instance, making the nitrate bath and keeping it in order has recently been brought under attention. I have never had any difficulty in doing this, but I should not object to pay a guinea or two to anyone who could teach me a better plan, or I would gladly contribute to an experimental committee fund. In the meantime, if those of your readers who are willing to "get information" can do so, it would affect the examination of such committees. My method is as follows, and is based upon hints and information given many years ago by Mr. Rejlander, and Mr. Blanchard in the News.

As I never make a new bath, but keep constantly renovating one I have had in use for years, I need not speak of the new bath, which generally works well. I keep two baths constantly going, which I use on alternate days, and sometimes change during one day of hard work, as I believe in rest for a bath. The moment a bath shows signs of being out of order, I pour it into an equal quantity of distilled water, add a few drops of a solution of carbonate of soda, and place it in a glass barrel on a shelf near the light, where it remains some weeks or months until required. I then always keep a bath, when not in use, in the light, which is constantly aiding it to throw down impurities. The barrel is covered with a piece of gauze or muslin, and there is constantly a slow evaporation going forward, which aids in removing ether and alcohol. When I require any of the solution for use, I withdraw it from the barrel by means of a glass tap about an inch from the bottom of the barrel, and immerse the barrel and tap both in boiling water to break the strength with crystals of nitrate of silver, and rarely find any difficulty in getting good results at once. Now and then I find boiling necessary, but not often; it is, however, always efficient. I scarcely ever add nitric acid to the bath, but when necessary I add a little tincture of iodine to the collodion instead.—Very truly yours,

AN OLD PORTRAITIST.

PRESERVING GELATINE.

Sirs.—It may be an advantage to those who are experimenting with gelatine, as well as those who require an antiseptic agent for other purposes, such as the preservation of albumen, paste, &c., to know that salicylic acid, used in very small quantities, preserves organic matters from decom-
position of any kind. A solution of gelatine, ten grains to the ounce, has been now standing several weeks on my kitchen mantelpiece, sometimes fluid, always tolerably warm, yet kept perfectly unchanged by one-eighth of a grain of salicylic acid per ounce.

Salicylic acid is an extract from coal tar, and is one of the commonest of carboxylic acids. It is without odour and almost tasteless, as well as non-poisonous. It is very slightly soluble in water, but more so in glycerine or oil, and produces, so far as I can see from my experiments, no chemical effect injurious to the reactions involved in photographic operations. This acid has been known for a long time, and was extracted from the oil of wintergreen at a cost of less than $1 per pound. It has, however, been found useful in photography, and is now made artificially in the presence of caustic soda, by which means it has been reduced in price as to become available for general photographic uses. It is sold by Hopkins and Williams at two or three shillings per ounce, whereas it once cost £10, and only a few months ago I paid twelve shillings.—I am yours truly,

W. J. Stilleman.

THE COST OF EXHIBITIONS OF THE PHOTOGRAPHIC SOCIETY.

DEAR SIR,—There was one statement made from the Chair at the Annual Meeting of the Photographic Society, touching the recent exhibition, which was not, I think, rendered very clear. When Mr. Hooper was deploring the cost of the last exhibition, the Chairman interrupted him with the remark that it had not cost the Society so much as the previous one, for whereas £28 was expended in 1874, as much as £126 (I believe these were the exact sums) was spent in 1873.

This statement was true enough, so far as it goes, but it was scarcely a business-like way of viewing matters, for although in 1873 as much as £126 was expended, the Society received in return £130 from admissions, sale of catalogues, and advertisements. Thus in 1873 the Society was actually benefited to the extent of a pound or two by its exhibition; whereas last year, a loss of about forty pounds resulted to the Society from its exhibition. It was a pity, I think, that the Chairman did not make this clearer to the meeting, especially after he had taken the matter out of Mr. Hooper's hands.—Faithfully yours,

H. Badem Prythead.

Proceedings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

The annual meeting of this Society was held in the Architectural Gallery, Conduit Street, on the evening of Tuesday, February 9th, Mr. J. Spiller, F.R.S., in the chair. The minutes of a previous meeting were read and confirmed, and the following gentlemen duly elected members of the Society: Mr. W. D. Bosanquet and Mr. M. P. Tench.

The Chairman read the Annual Report of the Council, which contained a memoir of the late O. G. Holender. The report will appear in our next.

Mr. Wager wished to ask three questions: first, he wished to know who was responsible for the photographic circuit sent out to members whose subscription had not been paid for the coming year, informing them that until it was paid they could not receive voting papers; second, why the voting papers were marked with certain initials; and third, why the marks on these papers were different.

The Secretary, at the request of the Chairman, answered that the circular was simply an extract from the laws of the Society. He was only the servant of the Society, to obey its rules; and he saw no means of doing this except by issuing the circular he had sent out. As to the marks on the paper, they were merely his initials, as a guarantee that the papers were sent out by himself. There was no difference in the marks, except in one case, in which a star was attached because a doubt existed as to whether the member to whom it was sent had paid his subscription.

Mr. Wager had seen three or four papers all marked differently, and it certainly opened a door to the suspicion that the secretary of the Society might be violated. The proper plan to secure certainty would have been to stamp each voting paper with the stamp of the Society. He still thought the circular offensive, and the proof that it was so was found in the fact that several old and esteemed members of the Society had resolved to resign in consequence. Country members were put to special inconvenience and disability, and the course was, he thought, most unfair and impolite.

Mr. Stilleman did not consider the circular offensive. Some people were annoyed when tradesmen mailed them in bills. As for him, he was in vain asked to mark on the voting papers; they could not be used, as they were all delivered sealed to the scrutineers, who burnt them as soon as they had taken the numbers.

A Member said that he had paid his subscription, and had received the offensive circular.

Mr. Prythead said the duties were new ones, and the Secretary was new to the duties, which had been unusually heavy, and some allowance should be made. Mr. Hooper, Mr. Bird, and Mr. Davis briefly spoke to a similar purpose.

The Secretary accepted the responsibility as it stood, and, except in relation to the accidental sending of a circular to the member who had paid, he contended that no other course was open to him. The report having been duly passed and adopted, the Treasurer read his report, from which it appeared that the balance to the good of the Society amounted to upwards of £534.

Mr. Hooper noted that the exhibition had been a greater cost to the Society this year than the previous year, and suggested that it would be important to try to make the exhibition as attractive as possible, without increasing the expenses.

The Chairman said that the expenses had been rather less, but unfortunately the income had been less in still greater proportion, so that the result to the Society were not so favourable. Mr. Howard suggested that in no manner could the funds of the Society be better spent than in the maintenance of their annual exhibition.

The Treasurer's Report having been received and adopted, and votes of thanks to the retiring officers passed, the Scrutineers' Report was received, from which it appeared that only 110 votes had been received. The elected officers were as follows:

President—J. Gissher, F.R.S.

Vice-President—J. Spiller, F.C.S.; V. Blanchard; Captain Abney, R.E., F.R.A.

Treasurer—R. W. Thomas.

The Chairman offered a few words of comment and explanation, in which he apologised to Col. Wortley for having nominated him without consulting him, and remarked that by doing so, and practically running two liberals against one conservative, they were naturally beaten. He referred to the circumstances of disturbance when he took the position of Chairman, and expressed his willingness to serve the Society in any office.

Mr. Blanchard expressed his wish not to accept the office of vice-president, but on being asked to reconsider his decision, withdrew his resignation.

A slight modification in Law 9 was passed, referring to the necessity of candidates for membership being submitted to the Council previous to ballot in the meeting, and notice was given of motion to alter the clause in Rule 11, in relation to voting, by 26 to 30, to a meeting to be held at the close of the March meeting. The object of the alteration proposed by Mr. Hooper is to entitle a member to vote who has paid his subscription for the past year, instead of, as at present, his subscription for the year just commencing.

* Two correspondents have written to point out that as, out of the 110 votes cast, Mr. Gissher received 65, leaving only 45 to be divided between the two candidates, it was unfair to suggest that Mr. Gissher's election was due to any division of his votes, as he must have had a majority of 30, even if only one other candidate for the presidency had been nominated. It is sufficient to note the matter here, without printing the letters and comments of our correspondents.
Mr. York then showed by means of the lantern some negatives of the Transit taken by Mr. Bruton, of Cape Town. The proceedings then terminated.

EDINBURGH PHOTOGRAPHIC SOCIETY.

An ordinary meeting of this Society was held in St. Andrew Square, on the evening of Wednesday, the 3rd inst., the President, Dr. Wilson, in the chair.

The minutes of the previous meeting were read and approved, and Messrs. James J. Fulton, Alexander Porteous, and W. Hannah were admitted ordinary members.

The President laid on the table an album containing a large collection of copies of the late letters of Mr. Bejlander, lent by Mr. Constable, and a fine collection of mounted prints by the same artist, lent by Mr. Elliot. He said that, before proceeding to the ordinary business of the evening, he thought it necessary briefly to allude to the loss which the whole photographic world had suffered by the death of Mr. Bejlander, and some others, one sense true, and the work of any particular photographer will be work of art, or not, just in proportion to the little or much artistic feeling that it has in it. The photographer with a true knowledge of art will conceive the picture in his mind, brain and soul, and work to make his camera reproduce the conception. This was the way Bejlander set about his work, and the result—those magnificent pictures on the table—was beyond all praise. If those were not art, then he was sorry for art, and had no doubt that some of the pictures were the best he had ever seen. He thought that Bejlander's works were especially of the wonderful command of light and shadow, and effect simplicity of composition. Bejlander trusted little to upholstery, and less to retouching, and, which was better, neither had to such an extent as was the case with many of the other photographers. He hoped that the motto, "Photography is a fine art," might be brought to a higher position than it had yet been. The objects of the Bejlander's works were more at home than in the society of men of the highest art fame. No one could be in his company for many minutes without feeling that he was in the presence of an artist in the truest sense of the term. Photography had before it a wonderful future, and the photographer who should have a fine artist for his model had done. He had set before himself an ideal to which he had worked up, and that with such success that some of the compositions could not have been better treated by even the best of the old masters. Photography in portraiture could only rise to art when the photographer brought a thorough knowledge of art to bear on his treatment of his model. This Bejlander had done, in a way which was worthy of all honour and patient study.

Mr. N. McCall wished to corroborate all that had been said in favour of Bejlander and his works. It amply proved the remark made by Mr. Bejlander, that he never had a model who was not a model of some sort, and that he always had a model upon whom the opinion of many, the art of photography, in every shape, would have to be based. Besides, the fund Northern heart not to be gladened by a true representation of a baby's very pleasant, though very evanescent, smile, merely because the background may not be so speckless or spotless as it should be? And have we not, amongst these of ladies and gentlemen before us, ample evidence for it, although Bejlander invariably aimed at something higher than fine manipulation? In the mere mechanical part of our art, he was a workman who needed not to be ashamed of his work? Probably you have seen the biographical sketches that have appeared in the journals, as well as the letter in the hand of a kind friend and patron, Mr. Constable. The writers all bear witness to his undoubted genius as an artist, as well as to his very genial and loving nature as a man. Mr. Constable has kindly sent me several letters written by Mr. Bejlander upon his death-bed; very, very appreciative and affectionate, and showing that he knew his Bejlander, containing an account of his husband's funeral, the expenses of which, I fear, leave but a small balance at her banker's account. A few friends, however, in Edinburgh are endeavouring to dispose of Prince Albert's picture by subscription, for the benefit of his wife. The proceeds of the subscription should go to the right and proper way to honour the memory of our departed and lamented brother, O. G. Bejlander.
that the members generally felt in the death of Mr. Rejlander, and that a copy should be sent to his widow.

Mr. Turnbull then read a paper on the "Various Styles in Portraiture" (see page 74).

Mr. Ross entirely agreed with Mr. Turnbull in objecting to retouching. He was glad to see, however, that the practice was gradually abandoned, or, at least, that those who had done most in this way were finding out that it would be better to do less. A really good negative did not need it, and operators should strive rather to make perfect negatives than trust to get their omissions partly cured by the art of the retoucher.

Mr. Macbeth thought Mr. Turnbull's paper was written in a capital spirit. If photographers would only aim at educating themselves, and then make the camera obey their wishes, there would be little need for retouching, and photography would go on with rapid strides to perfection. Mr. Rejlander owed nothing to retouching, and yet his work was such as to make even the best enby him.

Mr. W. Nelson had listened with pleasure to Mr. Turnbull's paper. He had no objection to retouching so long as the public insisted on it, but he thought the public ought also to be educated to the errors, and that the reputation of the person to whom allusion had so often been made, always took care to throw in a little light into their shadows, and he thought retouching to that extent was fairly allowable, and it might also be legitimate to use it in softening the hard lines, so long as the true texture was not hurt.

Mr. Norman Macbeth did not like to appear severe, but he regarded the practice of retouching as beyond condemnation. He would strongly press on the attention of photographers the importance of a more careful study of development. In this he was certain that it was rarely done, and as in the art of the master, to whom allusion had so often been made, always took care to throw a little light into their shadows, and he thought retouching to that extent was fairly allowable, and it might also be legitimate to use it in softening the hard lines, so long as the true texture was not hurt.

Mr. Ross hoped they would all lay to heart what Mr. Macbeth had said. He once got a picture from Rome. It was a first retouched specimen he had seen, and he wished it had been the last. It had no bones, no muscle, no nothing, in fact, that a picture of a man and gave rather the idea that the model had been a man of plastic putty, misused by a clumsy hand.

The usual distribution of prints was then made by ballot, and Dr. Nicol, the corresponding secretary, intimated that he had received from Messrs. Coxson, of Southport, a supply of their little almanacs; and as there were not sufficient to go over all the members present, he should give one to each of those who had drawn a blank; and he might say that, as each of the almanacs contained two pretty photographs, they would have cause to be well pleased.

A few thanks were then given to Mr. Constable, Mr. Elliot, and Mr. Turnbull, and the meeting adjourned.

Photographers' Benevolent Association.
The ordinary monthly meeting of the Board of Management was held at 174, Fleet Street, on Wednesday, the 3rd ultimo, Mr. Skinner in the chair. After the minutes of previous meeting had been read and confirmed, Messrs. Stevens, Lane, Dighton, Banks, F. Stockard, Patterson, and Miss Jones were duly admitted members of the Executive Committee. The Secretary was instructed to convey the thanks of the Board of Management to those ladies and gentleman who so kindly and efficiently contributed to the success of the entertainments at the General Meeting. The Secretary was also instructed to get a card of membership printed.

Two applications for relief were presented and considered.

Five pounds were voted for the relief of one applicant, who had been ten weeks out of employ, and had had his daughter and wife ill. For the relief of the other applicant a sum of money was ordered to be sent to a photographer in the neighbourhood, asking him to take a ticket for the destination of the applicant, this course being adopted on account of the unsatisfactory result given to those who had done most in this way were finding out that it would be better to do less. A really good negative did not need it, and operators should strive rather to make perfect negatives than trust to get their omissions partly cured by the art of the retoucher.

After the transaction of some routine business, the meeting adjourned.

Talk in the Studio.

Lantern Readings.—We have just received from Mr. Frederic York another of his excellent little adjuncts to successful lantern exhibitions, in the shape of a descriptive lecture to serve as a "lantern reading" for a series of slides illustrating the Indian Empire. It will prove very welcome to all interested in lantern exhibitions.

Designs for Magic Lantern.—A correspondent of the English Mechanic, referring to Mr. Biggs's recent paper on the magic lantern, quoted by our contemporary from the News, says:—"Will you permit me, as a mechanic and photographer, to express to you the pleasure that I have experienced in the way of doing that which is more difficult than it at first sight looks to be, to secure true geometrical drawing on a three-inch circle of glass. I would, were I possessed of a lathe with overhead motion and geometric chuck, take pieces of glass as flat as you please, I have three and a quarter inches and I have a black varnish of such consistency as to scratch cleanly, chuck them, and, with a fine-pointed tool, describe the required patterns; thus producing a negative which could be printed from direct. Such pictures I am certain would be—provided the varnish were such as to give a clean scratch—unreliable in anything I have ever seen. Any fellow-reader who could carry out the mechanical and artistic part of the idea, I would willingly assist with the photographic.""
HENRY SPINK.—The nitrate of silver obtained from boiling down a bath should be quite available for a negative bath; but if you have any doubt, use it for printing purposes and use fresh silver for the negative bath. Streaks in the direction of the dip under these circumstances are often due to scum on the surface of the solution.

PAPER BIRM.—It is very difficult to give general advice in relation to all that you contemplate. If you state any point or points upon which you are in doubt, we shall have pleasure in aiding you; but you will see, on consideration, that it is necessary we should have your plans before us before we can offer any opinion or suggestion. As to question B, we cannot give any certain answer. Of course the matter is a delicate one, and can only be determined by trial. Write to any of the gentlemen in question, and try.

J. EASTHAM.—We will write to you.

Several Correspondents in our next.

METHICROLOGICAL REPORT FOR JANUARY.

BY WILLIAM HENRY WATSON.

Observations taken at Braystones, near Whithaven, 36 feet above sea level.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

TINTED DRY PLATE FILMS—FLEXIBLE GLASS—IMPROVEMENTS IN PHOTOGRAPHIC BOOK ILLUSTRATIONS.

Tinted Dry Plate Films.—It is a circumstance worth noting by those who have little experience in dry plate photography that the tinting of the film, as now practised commercially, has the effect of rendering a longer exposure in the camera necessary. Those, for instance, who have been accustomed to underexpose plates, and have been using exposures of perhaps a few seconds only, will be considerably surprised to find, when developing a batch of films that have been tinted, that the pictures secured are considerably under-exposed. One cannot, it seems, attain one advantage without the sacrifice of another, and if we get rid of the objectionable backing, then longer exposure must be used or the glass must be thicker. All things considered, it is the tinted film we shall most prefer, because, if before the greater cleanliness and less liability to become spotted by dust particles, which are most difficult to avoid when one has to do with a layer of loosely attached pigment on the reverse side of the plate. The tinting of the film, as everybody knows, is for the purpose of rendering it more opaque, and thus avoiding the annoyance of the phenomenon of light and shade, by which the light can readily penetrate the film. If the coating of collodion could be made dense enough without the mixture of colour, such a course would be, of course, preferable, for it would then be unnecessary to sacrifice any of the sensitiveness of the plate, or have recourse to the employment of backing; unless, indeed, we can make some progress in the line of Dr. Lebmann Vogel's interesting experiments, which have proved that, under certain circumstances, the sensitiveness of bromide of silver is materially improved by the addition of colouring matter.

The day may come, perhaps, when we shall have dry plates fitted for all kinds of services at the disposal of the photographer; thus when he desires to depict an image in which there is a large amount of green light, he will employ a film which absorbs these particular rays, and is especially sensitive to green; when he has a red subject, he will make use of a film that absorbs red rays, and so on. If we can only get the colouring matter we now add to dry films to fulfil a double object, to render the collodion at once more impenetrable to and capable of absorbing light rays, and to be so tinted that Dr. Vogel has been able to do in his experiments with the spectrum, then, indeed, we shall be making a great step of progress in the matter. In the meantime, however, we would warn those who are not practised in dry plate photography to be careful to give good exposures to plates which have been tinted with any colouring matter.

Flexible Glass.—There seems some chance of a great photographic problem being solved, if what we have been recently told in the "Times" and "Athenaeum" should turn out to be true. For a long time past we have been looking for a substitute for glass, for a basis for collodion, which, while as rigid and transparent as that material, shall not be so brittle and fragile. The Vienna Photographic Society deemed the subject of such importance that two years ago they offered a gold medal and a sum of money to anyone who should bring forward a thin transparent film, tough and flexible, suitable for coating with collodion and receiving an image in the camera. Many experiments have been made to secure such a material. Gelatine has been used in every form and variety, and although most delicate and insoluble sheets may be obtained with it, these are found exceedingly liable to be torn, and also to swell and to absorb moisture in a damp atmosphere. Collodion mixed with castor oil, or some such material, is little better, for although it affords a hard, flexible mate-

rial, the same is endowed with little strength. Indeed, the only substitute of the kind we have for glass are sheets of mica, and these, as photographers know, are at times by no means satisfactory. But now we hear of a discovery which seems likely to be a great boon to photographers. We hear that a glass worker at Dresden, a Herr Meeser, brother of Messrs. Siemens, the celebrated firm of telegraph engineers in London, has been successful in producing a tough, malleable glass, which can be bent without breaking, and which may be produced in the thinnest sheets without being brittle. Ordinary glass is simply heated to redness, and on cooling it is annealed in oil, this process having the effect of greatly increasing the toughness of the material. The process is by no means an experiment, we are further informed, but "certain and unquestionable" in its results. If such is really the case—and there is no reason for doubting the matter—photographers have great cause for rejoicing, for a very large percentage of their productions are lost by the glass of their negatives giving way under pressure in the printing-frames, the trial through which clichés pass in pigment and collotype printing being often very severe. We shall have much pleasure in giving our readers further news of this matter as soon as more detailed information reaches us.

Improvements in Photographic Book Illustration.—We are glad to notice that Messrs. Ward, Lock, and Tyler, the well-known publishers, have taken up the matter of photographic illustration. A volume they have issued, under the curious title of "Treasure Spots," consists of a score of cabinet-sized photographs, printed by the Woodbury process. The best part about the volume is the way in which the photographs are displayed and mounted. A print simply pasted upon a sheet of letterpress, or surrounded by a margin of black printer's ink, of a different tint altogether to the photograph itself, is a most unsatisfactory illustration in a book, as has been pointed out in our remarks on the previous pages. In the case of this photographic book illustration in question, special attention seems to have been given to this matter, and the tint of the photograph is in perfect harmony with the printed margin that surrounds it. In this way a very effective publication has been produced, and one, too, which will pave the way, we think, to others of the same kind.

THE PRACTICAL PRINTER IN AMERICA.

XVII.

In the following chapter on printing with weak negatives Mr. Hearne enumerates a number of dodges which his experience as a practical printer has proved good. He has, however, omitted to refer to a point of primary importance. One of the most important aids to brilliant contrast with weak negatives is the use of a lightly sailed and highly albuminized paper. A River paper coated with undiluted albumen, containing not more than four or five grains of chlorids of ammonium to each ounce, will be found very valuable with thin fine negatives. This albumen should be made strong on neutral or slightly acid forty-grain bath, or, if the bath be not neutral or alkaline, the paper should be fumed. Weak negatives gain greatly by printing in the shade. We now let Mr. Hearne speak.

"As is the case in printing intense negatives, so paper should also be prepared especially for printing weak negatives. White paper should be silvered for a specified time on a strong silver plate; both by from forty to one hundred and eighty seconds, on a bath from 45 to 80 grains strong of nitrate of silver to the ounce of water; but the strength of the bath and time of floating should vary according to the temperature of the weather, class of negatives to be printed, &c."

"When the paper is ready for fuming, it should be fumed not less than fifteen minutes, and often for half an hour. Sensitive albumen paper, when it has been sensitized
the day before, is excellent for printing very weak negatives, giving much bolder prints than it would if it were freshly sensitized. The paper for weak negatives, like that for intense negatives, should be kept by itself, and for this purpose have a box or drawer labelled 'Paper for Weak Negatives.'

"There are only a few negatives out of a day's printing that require any special treatment before printing."

"In by far the majority of cases the beauty of the negatives consists in their thinness, unless they are so thin as to give very flat prints. In a thin or weak negative, such as one as I at present have in my mind's eye, its beauty consists in detail throughout in the strongest high-lights, as well as in the shadows; also in its colour, lighting, &c. In exposing there has been plenty of time given to the negative, and consequently detail is found in all the shadows and draperies, with the exception of three or four places in the deepest shadows, where there is no detail, and which accounts for the brilliancy of the negatives.

A cool grey colour to the deposit adds greatly to the beauty of the negative, as well as to its printing qualities.

"A nicely lighted negative, besides being beautiful—as we judge it by looking through—also prints better, because then there are left, by the artistic taste of the operator, a negative's saving graces, such as quarters in the hair, which by contrast are generally close to that part which has been powdered, and is photographically full of detail; and when we admire beautiful negatives, one of the first parts we look at is the hair, especially if it is a lady's, and we very often involuntarily exclaim, 'How brilliant and full of detail the hair is!'"

"Now prints from these negatives, which are so brilliant, bold, and full of detail to the eye, very often astonish us, on account of their being exactly opposite to what we had been led to expect when we looked through them, and at first the photographic printer is bothered a little to account for it. This is accounted for as follows: they printed too fast, and the negatives may not, perhaps, have the photographic colour which produces the best print. To print slower, and to give the photographic colour they require, coating the back of the negative with yellow varnish has been advised, and I have tried it with considerable success; but the prints have a look of forced boldness and coarseness which spoils them in the eyes of most printers. Undoubtedly the yellow colour of the varnish is not what we wish. Nothing is better to give a good printing quality to the negatives than white tissue-paper."

"The way to overcome this rapid printing is to print either in the sunlight or under several times as long as we have used as eight or ten—the latter when you wish to place the board in the sunlight; and, besides printing slower, they will also print better. When a negative is very thin, we generally print it under a porcelain-glass, in the sunlight, and the prints are thus very much improved. Try it. Printing under several pieces of the greatest of window-glass is a very good thing, as a safeguard of the prints."

"A way which I very often try, if the negative is not too thin, is to coat the back of it with ground-glass varnish, and which I can vouch for as a good thing. The ground side of a ground-glass laid close to the negative is also excellent.

"But a negative which has flatness throughout, without any boldness worth mentioning, cannot be doctored by any such simple treatment as the above. More decided measures will have to be resorted to.

"One way to improve flat negatives is by the use of the blue-paint dodge, which has been so repeatedly described. I have very often laid it all over the face of the negative, but on the unvarnished side of it, and after removing what may be over the eyes, then have printed it, after having covered the back of the negative—or, better still, the printing-frame—with tissue-paper.

"Then a very good way to allow the shadows to print up under tissue-paper, while the face is protected, so as to make them print bold (which they will do if printed under a piece or two of tissue-paper), is to cover the whole negative-board with tissue-paper, and then lay a dark cloth on that part which you wish to be shaded, moving it every few minutes while there. By a little ingenuity in the way of arranging tissue-papers they can be made to answer a variety of purposes."

The method of producing a duplicate image of the negative at the back by means of the powder process will also be found very valuable, and should not be forgotten.

**THE RELATION OF LIGHTING AND EXPOSURE TO TEXTURE.**

**BY G. CROUGHTON.**

Mr. Neilson, in a short but able article contributed to the [Photographic News Almanac for this year], has struck a key-note worth following up. The article in question is upon developers and texture. It is, as he says, a somewhat neglected subject, but it is one which should demand serious attention; for there are, in my opinion, few things which have lately come into universal use among photographers which have done so much to photography artistically, and are certainly utterly destructive to texture. I allude to retouching upon the negative, and the use of reflecting screens, or, rather, I should say, the abuse of these, for both in their places are useful, and, properly used, may help us to secure natural texture, whereas we could not get it without them.

"It may be asked—"Texture upon a photograph means what different thing to texture in oil painting or water-colour drawing. In oil or water colours the artist uses certain means for obtaining a natural texture (in flesh painting, we will say); he has to load up his colours, glass, and scumble, and so get a texture upon his canvas, which, when looked into, is anything but the texture of the smooth skin of a beautiful young lady, yet when seen at the proper distance gives that texture with all its soft, glowing colours and gradations to the life. It requires no departure from nature to get natural texture in a photograph."

Photography has been admired by artists for its wonderful reproduction of the texture of different fabrics, which has been used by them as guides on account of its accuracy. It has failed so completely at this that no effort of light or the fact of yellow being reproduced as a dark instead of a light colour, all flesh, however fair, being made up of yellow to a much greater extent than an inexperienced person would think.

To mend this inaccuracy retouching was called in, and if it had been confined to this, and gone no farther, it would have been a gain instead of a reproach; but with some persons it seemed that once the pencil was in their fingers they did not know where to stop, and the result, in nine cases out of ten, is the destruction of all natural texture, and the substitution of a mechanical stipple all over the face, representing to the eye nothing so much as a plaster cast or a face cut out of stone. How many times have I heard the public protest this, but in terms which should be their greatest condemnation? "How beautiful it is—just like a statue!" Not "How like life!" simply because they were not like life. In these over-worked abominations we have an incongruity most offensive to an artistic or educated eye—a marble head with drapery the fabric of which is reproduced with the greatest fidelity.

The remedy in this case is easy: do not overwork the natural texture in the negative; mend all defects, matching (as well as human eyes and hands can do) the texture, and..."
do not attempt to substitute another, for all such attempts must end in failure. There is nothing so beautiful as the texture of flesh in a good negative, and it is worse than folly to do away with it and substitute a stippled mechanical one, which must end in smooth hardness, making the flesh look like polished stone.

Before proceeding to show how the use of reflecting screens has produced such destruction of texture in flesh, I would wish to say a few words as to the best means of securing a natural texture in the photograph. Mr. Neilson, if I understand his article aright, says it is to be secured by using a strong developer after a weak one; in my experience it is entirely a matter of lighting and exposure. Given the right lighting and exposure, I will guarantee to obtain an effect with any developer. Try a sitter in the ordinary ridge-roof gallery, blocking out all side-light. Look at the face; the more front the light, the less marked the features and texture of the skin. Now close all front light and use only side light, and see how all is reversed. The texture of the skin is exaggerated, and every pimple looks at least twice the size it is. Every photographer who is in the habit of taking the side-lighted photographs, or the so-called Rembrandts, will at once recognise the accuracy of this description. With the light from behind the sitter, the accidental marks and texture are generally much exaggerated; and if the intensity of the light be not modified in some way, it will give no end of work to the retoucher. It is for this kind of portrait that the use of reflecting screens has been mostly recommended; and, if judiciously used, they do a great deal of good in softening the heavy shadows, and getting rid of the exaggerated texture caused by the extreme side light.

Over-reflection will give exactly the same effect as over-touching—the destruction of the natural texture—in the same way as the front-lighting. In my own practice I never use a reflecting screen at all; if a judicious combination of side and front light, and a bit of good development, there is a much better way of doing it; and for the Rembrandts I close up all light at the camera end of the gallery, bringing the sitter half-way up, leaving the side light behind all open, and softening the shadow with a high side light, or combination of top and side, in advance of the sitter, as the face may require, and with this lighting can always secure texture if the right effect is desired.

In my experience the exposure has as much to do with securing natural texture as the lighting. An underexposed negative which has to be forced in developing will be coarse in texture, while over-exposure will be utterly destructive to all texture.

Mr. H. F. Robinson’s lesson in the same Year-Book upon softness, taken with Mr. Neilson’s underexposed, is a salutary dose which photographers will do well to take; for there is just as much want of texture in the over-softness condemned by Mr. Robinson as in the hardness condemned by Mr. Neilson. But, while agreeing with Mr. Neilson so far, I must say, with all due deference to him as an artist and a photographer, that I cannot agree with him in seeking texture in developers. Texture is not a photographic model, and can be secured by any developer provided the lighting and exposure have been properly adjusted.

**STEREOSCOPIC TRANSPARENCIES.**

By F. Howard.*

In calling the attention of the members to this phase of photography it must be understood that I approach the subject particularly from the reproductive aspect, and I am afraid that in venturing on this subject I am calling attention to what has not been a popular feature of photography, or rather, I should say, to what has been a neglected one.

For several reasons the stereoscopic has been very much favoured partly because of the hundreds of bad and inferior instruments and slides with which we were flooded, and partly also from another cause, viz., the bad taste displayed in many of the subjects chosen. Bad instruments fatigue the eye, and bad subjects give the whole thing a bad name. Good glass transparencies are, on the other hand, if viewed in a good instrument, always a source of pleasure; and it is from this circumstance, and the fact that they are much fonder of glass transparencies than of pictures, that I have for some time past endeavoured to obtain the requisite knowledge and materials to amuse myself with their production.

The increased area of work which stereo. pictures offer, viz., marine and instantaneous effects, also makes the subject more attractive; but since Mr. Bresson’s picture very little has been done, and it is still almost untrod ten ground. I have taken the trouble of going to the trouble, and have obtained a number of transparencies by printing in the camera. My reasons for doing so are:—Firstly, because printing by superposition necessitates cutting the negative, and it is also necessary that the negative should be exactly the same size you wish your transparencies to be, and this is not always convenient. Printing by contact is very likely to damage the negative, and the preparation of plates is attended with a much more considerable consumption of time; and when the amusement is only to be indulged in at spare hours, and those are not many, camera printing becomes more easy.

I will now state the method I have followed in producing the slides which I now show you; it is also necessary that I inform you that all the slides I exhibit this evening are printed in the camera. I have adopted for the camera 7 x 5 inches, and for allowing some margin, not too large. The width between the lenses is three and a-quarter inches.

The camera I would recommend is a rigid one, or at least one without a bellows box, because of the tendency to harbour dust. The negative for printing a stereo. transparency from should be as perfect as possible, and dust is of the greatest importance. Minute defects which would be observed in a paper print will on glass show most annoyingly.

There is a legend that the operator who prepares plates for exposure and printing by the albumen process is compelled to demure himself of his clothing, grease his hair, and hold his breath to avoid dust; but for the truth of this I cannot touch. I can certainly do without the fine

In my opinion the exposure has as much to do with securing natural texture as the lighting. An underexposed negative which has to be forced in developing will be coarse in texture, while over-exposure will be utterly destructive to all texture.

Mr. H. F. Robinson’s lesson in the same Year-Book upon softness, taken with Mr. Neilson’s underexposed, is a salutary dose which photographers will do well to take; for there is just as much want of texture in the over-softness condemned by Mr. Robinson as in the hardness condemned by Mr. Neilson. But, while agreeing with Mr. Neilson so far, I must say, with all due deference to him as an artist and a photographer, that I cannot agree with him in seeking texture in developers. Texture is not a photographic model, and can be secured by any developer provided the lighting and exposure have been properly adjusted.

---

* Read before the South London Photographic Society.
vigorously to allow of the printing being carried far enough, the same as in paper prints, and your negative shadows perfectly clean and free from fog. The various colours are much influenced by the exposure and the method of development. Iron developer with varying exposure will give brown tones; pyrogallic development with varying exposure, black and bluish tones. Toning with gold and platinum will give black and blue-black; bi-chloride of mercury and ammonium will assist in giving sepia tones from a vigorous negative.

Now as to the best kind of glass. Remembering that you have to mount two pieces together, the thinnest glass you can obtain is that most desirable, but the thinnest glass means a very imperfect in quality; but a little increase in price will allow of its being selected, and that which is somewhat imperfect can be utilised for mounting as imitation ground glass. This glass is of French manufacture, and is, I think, only to be obtained at one house in London. The thin ground glass can also be obtained, I believe. I have found it a good plan to make a varnish of three grains of white wax dissolved in an ounce of ether or chloroform; this added to an amber varnish gives a very good imitation of ground glass, and is a very satisfactory method.

In printing-in clouds much the same method is adopted as with paper prints, viz., masks are used to protect the sensitive surface, and the printing is done in a diffused light. The plates must be examined when warm for the first time; but, like other difficulties, it is soon surmounted. A lithographic card is a great finish to the mounted slide, and also a great protection. I do not think these are to be purchased. I make my own; that is to say, I lithograph the design and have it printed, also the binding paper with a border.

**SUGGESTIONS ON RETOUCHING.**

In the course of an article on retouching in the Western Photographic News, the following suggestions are given:

"1st. Practice with the pencil until perfect precision and delicacy of touch are attained."

"2nd. Use the 'hatch lines' more than the 'stipple dot' wherever it is possible."

"3rd. Turn the negative partially upon its side while working the upper portion of the face, to enable the work to preserve the same direction as the natural lines of the face."

"4th. Work upon the forehead, the least about the mouth, eyes, and chin."

"5th. The darkest parts of shadows are near the edge, the centre being illuminated by reflected light."

"6th. If it becomes necessary to lighten up a shadow, do so by working most on its reflected light."

"7th. To give relief, brilliancy, and effect, work just as little upon the shadows as possible."

"We will suppose the retoucher to have before him a

**PERFECT NEGATIVE:**

that is, one that has bright and strong high lights, delicate and yet sufficient shadows, possessing texture and fine gradation of lights and shades throughout the whole, and an expression of face all that could be desired. Now, I would say to him, 'By all means leave those shadows alone.' Work out the spots and objectionable points in the light until they become round, smooth, and nicely blended with surrounding parts, and then leave it. Endeavour not to make a stroke more with the pencil than is necessary. And the more delicate and sure each stroke the finer the result. Again, we will suppose that we have before us a

**VERY INTENSE NEGATIVE:**

one that has large thick patches of light, without suitable gradation into the shadows, with shadows unilluminated and too dark. The most that can be done in this case is to make the brightest lights much brighter at their very highest points of light. For the shadows, if too dark, work as much as possible in the illuminated portion, and just as little between these two extremes as the negative will admit. Now we have a

**THIN FLAT NEGATIVE,**

one that would make a better solar than contact print, neither bright light nor deep shadow, a tameness that would invariably produce a muddy, expressionless print. Now, as we cannot make the shadows darker only by contrast, it follows that the brighter we make the lights the darker the shadows will appear. The quickest method I have ever found to do this, is to draw an unlimited number of fine lines over the thickest portions of forehead, cheek, nose and chin—lines so fine as not to be discernible to the eye, only in effect; and when the negative is sufficiently dense by this method, then fill the interstices as carefully and abundantly as though first commencing work, smoothing the whole face, with the thought of giving a more perfect idea of the natural form of each feature. The smaller space this lining and interlining takes up, and yet be nicely graduated into the half-lights, the better."

**CHROMO-PHOTOGRAPHY OR PHOTO-MINIATURE.**

BY A. LIEBERT.*

Preparation of Paper.—Unbennetonized Steinbach paper is floated upon a gelatine bath for a period of three or four minutes, the gelatine surface downwards. The bath is thus made up:

1 litre Chlorified water
10 grammes Chloride of ammonium
3 grammes White gelatine
10 grammes Citric acid
18 grammes Bicarbonate of soda

The drying of the paper should take place in a warm room.

The most beautiful and richest tones are secured with an ammonia silver bath; this glass is uncoated in the advantage that it allows of less intense negatives being employed; the depth of tone is considerable, and the lights are white and brilliant.

The ammoniacal silver bath is thus prepared. In one bottle there is placed a solution made of:

160 grammes Nitrate of silver
1 litre Water

The half of this solution is put into a bottle; to the other half is added in small quantities so much concentrated liquid ammonia that the precipitate forms at first is again perfectly dissolved, a circumstance that is brought about by continually shaking the liquid. As soon as the latter begins to get clear again, the ammonia should be added very slowly and in very small quantities so that the process then comes into the solution. Half of it is taken, and so much pure nitric acid added that blue litmus paper dipped therein changes to a fresh red colour. All the solutions are then poured together, and the mixture filtered.

As soon as the bath blackens after being some time in use, it may be cleared by adding a few drops of nitric acid and filtered. The bath must not be exposed to daylight, as it is particularly sensitive, and no more should be prepared at a time than is absolutely necessary. The paper, as before stated, should be permitted to float upon the solution for three minutes.

Prints produced by means of this bath do not become much lighter in the after processes, and for this reason must not be much over-printed in the frames, as is the case with albumen pictures. The silver bath must always be in good filtered condition, and kept in a well-stoppered bottle, otherwise a film of metallic silver is forced which is the cause of spots in the prints. The toning and fixing of the prints are carried on in the same way as usual.

In producing photo-miniatures two prints are necessary from the same negative. The best: format for these pictures is 21 by 27 centimetres or 24 by 30 centimetres. As it is inconvenient to retouch to any extent, it is well to employ good, sharp negatives, if possible with a dark

*Photographic News. 40.
ground. Both of the prints must be a few centimetres larger than the finished picture is required.

We will suppose that we have to print from a negative 24 by 30 centimetres. One of the prints is put in a damp condition upon a glass plate measuring 21 by 27, the edges are folded underneath, and gummed down with thick gum, so that the picture when dry lies perfectly flat.

In four little porcelain dishes, four pigments are mixed, as under:

1. Naples yellow, about 4 parts
2. Red madder 1 part
3. Carmin 1 part
4. Sepia 4 parts
5. Red ochre 1 part
6. Red madder varnish 1 part
7. Carmin varnish 6 parts
8. Naples yellow, mixed with sepia, 1 part
9. Naples yellow, mixed with sepia, 1 part

With a somewhat thick camel's hair pencil, all the flesh parts of the portrait are covered with No. 1 mixture. All the applications must be made quickly, and in a sweeping manner, without any pause or hitch, so that on looking through the print under, mixed with colour are visible. When the first thin film of colour has dried, there is applied, one after another, three coatings of No. 2 mixture. The shadows under the eyes, the nostrils, ears, and chin are strengthened by a coating of No. 4 mixture, and then the whole is allowed to dry.

For blue eyes, cobalt blue may be employed; for grey, Indigo; the browns, burnt Sienna, with a little umber or sepia. But all these colours must be applied in a very dilute form. The point of light in the eyes must be delicately put in by means of Chinese white. Blonde hair is painted with yellow ochre or burnt Sienna, brown with umber, which may be made darker and blacker by the addition of sepia, &c.

The drapery is covered with smooth tints. Such stuffs as are not rendered well by photography, and are represented dark in the print—such as red, yellow, green, &c.—must be blocked out in the negative, so that they can afterwards be tinted the right colour. White lace is put in with the aid of white pigment. Gold ornaments are put in with Indian yellow or gamboge.

The background is covered with an even tint, according to the subject, mixed with sepia or Van de Velde brown, mixed with some vert de veste, may be employed for the purpose with advantage. The colours must be used in a dilute form, and be applied two or three times over, in order to secure body.

When the first picture has been painted and finished, it is rendered transparent, and attached to a glass plate. To do this, the following mixture is requisite:

- Canada balsam: 100 grammes
- Spermaceti: 75 grammes
- White wax: 25 grammes

This wax is heated in a water bath, and, on becoming cold, forms a stiff paste. To cement the picture, a small piece of apparatus is necessary such as shown in the cut here given. It consists of a little iron table, F, G, H, I, of about thirty by forty centimetres, which stands upon four iron feet fifteen centimetres in height. Under the table are put four spirit lamps, D, E, with an arrangement for raising and lowering the wicks, so that the flames may be increased or decreased as may be necessary. A and A are scrapers having their lower margins fitted with very soft chamois leather. The dish C contains the abovementioned mixture, and a spatula H. In the drawer are contained other things necessary for the process, such as brushes, colours, and the like.

The coloured picture attached to the glass is separated by means of the blade of a knife; the margin is cut through all round, leaving two or three millimetres adherent to the plate.

Upon the iron plate B is put a sheet of blue paper, and upon this a well-cleaned sheet of patent plate glass. As soon as the glass plate has become pretty warm, it is brushed over with the wax mixture, the same being equalized by means of the spatula. As soon as the mixture has become fluid the picture is placed face downwards upon it, and the air-bubbles are then pressed out by the aid of the two scrapers before mentioned. After the lapse of ten or fifteen seconds, the picture becomes perfectly transparent. The spirit lamps are then removed, the picture is lifted up, and a further sup. of wax is put upon the plate; the picture is again pressed down upon it, and rubbed well in order to prevent too much of the mixture becoming absorbed, and to avoid the formation of air-bubbles. When the plate has become cold, it is taken from the table and its surface is cleaned first with turpentine and then with alcohol.

The picture now appears flat and without vigour. To give it the necessary vigour and brilliancy, a second print must be laid under it. This is prepared as follow:

The glass plate upon which the first picture has been coloured is covered with a thin film of gum solution, and the second print is now placed face upwards upon it, and rubbed in all directions, so that it adheres well in every part. After drying, the print is coloured quite superficially. The outline of the hair and the shadows of the face are tinted light blue, the darker ones being strengthened with sepia. Cheeks and lips are treated with a mixture of zinnabar and carmine, and over the whole of the flesh is laid a thin layer of Chinese white, in order to blend the colours together. Blonde hair which has come out too dark is covered, in order to lighten it, with a mixture of white and chrome yellow. Certain portions of the garments are strengthened, especially in the shadows, with colour that has been mixed with gum-water. The background is treated with pastel with the finger in such a way that the tone around the head is light, and increases in depth towards the margins of the prints.

On the margins of the picture are cemented strips of cardboard from one to two millimetres in thickness, and the first print, which has been rendered transparent, is placed upon it so that all portions accurately coincide.

The slight space existing between the two prints gives the finished picture a beautifully harmonious character. It is possible, if considered desirable, to mount the lower picture upon stout cardboard instead of upon glass, and upon this, in a dozen places in the deep shadows, to put little bits of cardboard to act as a support to the top print; but these supports must not, of course, be visible.

When everything has been thus carefully carried out, the margins of the double picture are skilfully covered with paper, so that their relative positions shall not change, and no dust penetrate between. It is the best plan to mount such double pictures in a velvet frame, or passepartout.

DISEASES OF PHOTOGRAPHERS.

A correspondent on another page suggests that a series of articles on the diseases to which photographers are peculiarly liable should be introduced. We have already expressed a like opinion, and we repeat our suggestion by mentioning the names of several gentlemen, who have been well known in connection with the art, who are alleged to have been the victims of one painful and not very common malady. We may say at the outset that we do not think that there are any diseases to which photographers are, as photographers, especially liable, or to which the practice of photography is directly, or necessarily subject to mental strain, or times unhealthy atmosphere, irregularity of hours of refreshment, and other causes detrimental to vigorous health, to which photographers often submit themselves, they suffer in common with many engaged in other avocations; but these influences, whilst undoubtedly injurious to health, are not entirely inseparable from the practice of photography.

In regard to the cases cited, we can set our correspondent's mind somewhat at rest. There is an error in his information. Mr. Rejlander never suffered from Bright's Disease; his death resulted from a not less painful, and probably equally fatal malady, diabetes, which, although essentially different, is, like Bright's Disease, a disease of the kidneys. We desire our correspondent to turn the pages to enter into the technicalities of disease; but we may briefly state that in the latter disease these organs, instead of secreting albumen and eliminating urea, perform exactly the opposite function, discharging the albumen and allowing urea to be absorbed into the system, eventually producing blood-poisoning. In diabetes there is a tendency to convert everything into sugar, which finds its discharge through the kidneys. The death of Mr. T. R. Williams was due to the latter malady. Certain circumstances connected with the illness of Mr. Lacy, to whom our correspondent makes reference, led us to consult with an eminent physician who had made Bright's disease a special study, in order to ascertain whether any of the influences to which photographers were subject should render them specially liable to this malady, and we received his assurance that he saw nothing whatever in the occupation or influences affecting the photographer which should in any way especially tend to the disease in question.

The photographer is, as we have on former occasions remarked, subject to the pressure upon his nervous system involved in the exercise of a profession causing at once some strain on the scientific, artistic, and social capacities. The heat of the studio and the fumes of the dark room are at times depressing; and, probably more injurious than all, the photographer often continues under these depressing conditions, forgetful or regardless of the necessity of regularity in taking refreshment, and so invites dyspepsia and its attendant train of evils. But all these are common to many pursuits, and may to a large extent, by resolutely judicious men, be avoided. To special diseases the photographer is in no unusual degree liable, and as the notion that he is so is in itself unwholesome and depressing, we recommend our correspondent, and any who may for a moment have shared his notions, to dismiss them as without the slightest foundation.

PHOTOGRAPHIC EXHIBITION IN BRUSSELS.

We are informed that the Belgian Photographic Association will hold its first exhibition at Brussels in July next, under the patronage of the King. The collection of pictures will be exhibited at the Cercle Artistique et Litteraire (Literary and Arts Club), in Brussels, between the 15th July and 15th September next.

Any inquiries should be addressed to the Secretary, M. Rommeiaere, Rue de Namur 44, Brussels; but we very briefly state here the principal conditions of the exhibition. Application must be made for space by intending exhibitors not later than the 1st May, and a charge will be made at the rate of five francs per square metre, half the amount due being paid on the 15th May at latest. The exhibition will be opened by the Minister of Public Instruction, on the 1st July, carriage paid, with the proper advice, the name of each subject and how it was produced being included in the information given.

A hanging committee will decide as to the fitness or otherwise of the pictures for exhibition, and foreign exhibitors will be compensated by medals in the following branches of the art, viz., heliographic engraving, hellotype, Woodburytype and albumenized, processes and carbon photography, silver printing, and photography upon glass or porcelain. Moreover a medaille d'excellence will be offered to the exhibitor whose work most merits.

The jury for making the awards will be composed of eleven members, of which five will be foreign. There will be no charge for the sale of the pictures exhibited, but a lottery will take place at the close of the exhibition, the works chosen being paid for by the Association. All pictures must be withdrawn at the cost of the exhibitor a week after the close of the exhibition.

ON THE PRECIPITATION OF SILVER FROM ITS SOLUTIONS BY COPPER.

BY WILLIAM HENRY WATSON.

The method of precipitating silver from solutions of its salts by copper or zinc is unquestionably one of great utility to the photographer, and a great improvement on the processes which used to be adopted.

\[ \text{Ag NO}_3 + \text{H}_2 \text{O} + \text{Cu} \rightarrow \text{Ag} + \text{Cu NO}_3 + \text{H}_2 \text{O} \]

This action is rapid, for immediately the copper touches the silver solution the decomposition takes place. The precipitate formed is repeatedly washed with water, and finally dissolved in moderately dilute nitric acid to ensure it as silver nitrate. It has been observed, however—and upon the subject I have made experiments—that along with the metallic silver there is generally precipitated more or less cupric oxide, so that the silver obtained by this process is not in an absolutely pure state, but contaminated with copper; and on dissolving in dilute nitric acid the result is a mixture of silver nitrate and cupric nitrate, thus unfit for many experiments in which silver nitrate is required. The results of my experiments alluded to above have been as follows:

A solution of silver nitrate, containing 0.5 of Ag NO₃,
100 of water, was prepared and used during the experiments below, a sheet of copper being used as the precipitant. The precipitate was washed till there was not a trace of Cu(NO₃)₂ present, dried, and examined.

Cupric oxide found in 100 parts of precipitate.

</tbody>
</table>

Hence 100 parts of the precipitate would furnish, on treatment with nitric acid,

\[158.23 \, \text{Ag NO}_3\]
\[5.86 \, \text{Cu (NO}_3)_2 \, + \, \text{H}_2 \text{O} \, \text{.}

163.79 total.

It has been suggested that the precipitation of the cupric oxide along with the metallic silver is due to the action of atmospheric air in absorption, and experiments have generally agreed with this view. If, again, the copper be exposed to the air during the process, the amount of cupric oxide precipitated is increased. Thus it will be seen that we do not arrive at pure silver by precipitating and carefully washing the precipitate in water, but that it is requisite to wash it with dilute hydrochloric acid, in which the cupric oxide is readily soluble, while the metallic silver is not soluble. Adopting the view that the precipitation of cupric oxide is mainly due to atmospheric oxygen, it seems probable that by boiling the solution of silver salt, and thus expelling from it much of the gases in absorption, prior to commencing the process of precipitation, the cupric oxide formed would be considerably diminished.

I may add that these remarks apply to precipitation by zinc as well as by copper.

**EXPERIMENTS WITH IRON DEVELOPERS.**

*Bulletin de l'Association Belge.*

Some experiments have been undertaken by us with the view of discovering what are the most suitable bodies to be introduced in the composition of developers made with iron salts, and to find out the proportions in which these should be mixed in order to produce the best results.

In the experiments made, all of which have been conducted by means of the ordinary wet process, we have worked by comparison. Two clichés produced under identical conditions were developed by different developers, the one of these solutions being a standard, the other, one whose qualities it was desired to find out.

In order to obtain two latent images as exactly alike as possible, we made use of a binocular camera, and obtained upon a plate measuring nineteen centimetres by eleven centimetres the double image of some objects grouped before an apparatus, in the same way precisely as when a stereoscopic negative is taken.

To develop the two latent images obtained, there was placed, first of all, across the middle of the cliché, as it came out of the camera, a strip of glass, which divided the two halves, and allowed the developer to be poured upon one portion without developing the other, which was treated as soon as the first picture had been finished. This plan was attended with some inconveniences, and for this reason was not always used. Every time that it was necessary to work with accuracy and precision, the following method was substituted, the results of which were far more trustworthy.

The plate which it was proposed to employ was in the first instance scratched with a diamond across that place where, later, its division was contemplated, to separate the two images. The plate was then in a condition to be easily broken on coming out of the camera, so that it was possible to develop the two images separately.

Finally, to take the experiments in a certain order, we examined, successively, the influence upon the period of exposure, and upon the nature of the images produced by—

1. The quantity of sulphate of iron.
2. The acids introduced into the developer.
3. The nature of the iron salt employed.

**The influence of the quantity of sulphate of iron.**—We have found, after many other investigators, that the quantity of sulphate of iron contained in the developer exercises a very great influence upon the nature of the negative produced. Whilst a developer containing but a small quantity of sulphate only gives rise to a faint image of a violet transparent character, those of a more concentrated nature produce negatives of considerable vigour and opacity. With a dilute liquid the image develops slowly, whilst with a stronger solution the plate is instantly developed. A weak solution penetrates into the collodion, and produces a deposit of silver throughout the whole thickness of the sensitive film, while a concentrated developer which acts briskly, only gives rise to an image upon the surface of the cliché.

Between certain degrees of concentration the negative grows in intensity according as the amount of sulphate of iron increases. This difference in intensity, very apparent in developers which contain only moderate quantities of sulphate of iron, appears to be less marked when the concentration of the liquid is increased, and when developers are employed containing exaggerated quantities of sulphate; indeed, reverse results are at times produced. In this case the developer by strong solutions are less vigorous than those obtained by dilute liquids.

Clichés secured by the aid of developers more or less concentrated differ not only as regards the intensity of the images obtained, but also in the physical nature of the particles of silver deposited.

When the proportion of iron contained in the developer does not exceed certain limits, the metallic particles, which together constitute the cliché, appear in general to be large in the proportion as the developer employed upon them is more concentrated, and there seems to exist up to a certain point a relation between the size of these particles and the degree of concentration possessed by the developer. The cuts here given convey some idea of the aspect of the particles viewed under a microscope capable of enlarging 800 diameters. Fig. 1 is a cliché obtained by means of a developer containing half per cent. of sulphate of iron. Fig. 2 is a cliché secured by the aid of a developer containing eight per cent. of sulphate of iron. The mean dimensions of the particles of silver in fig. 2
DEVELOPMENT BY VAPOUR.

Dear Sir,—The time is come when amateurs would do more in photographic work, but they must be enabled to do so without soilng a white kid glove. And why not? What is wanted is the developing and fixing by vapour, such as was obtained by the old mercury and iodizing boxes used in the Daguerrotype process; and as alkaline or acid vapours can be produced easily, some photographic chemist should fix his attention to what vapours shall produce the picture on the sensitive plate, and so fixed that all the future operations,—printing, enlarging, &c.—could be done by the professional.—Yours truly,

J. SOLOMON.

There is undoubtedly room for experiment in this direction. It is probable that a bromide plate may be developed by the fumes of ammonia, and we have ourselves successfully intensified a negative by submitting it successively to the fumes of mercury and iodide.—B.N.

DISEASES OF PHOTOGRAPHERS.

SIR,—I see it mentioned in your contemporary that the death of the late Mr. O. G. Rejlander was due to a painful disease known as "Bright's Disease," and another photograph is also mentioned who recently died from the same uncommon ailment. This recalls to my mind the fact that Mr. Lacy, a photographer of considerable mark in the Isle of Wight, also died of "Bright's Disease," and I have heard it rumoured that the death of the late Mr. T. R. Williams was from something of a similar nature. As these cases are of which we hear, it is not unnatural to speculate on those which do not come under public attention, and to ask if there is anything in the practice of photography which brings about or predisposes the victim to this fatal illness? Amongst the many good services your journal has done the lovers of our art, I think the issue of a series of articles on the diseases to which photographers are especially liable would not be the least.—I am, sir, yours gratefully,

L. L. P.

MECHANICS FOR PHOTOGRAPHERS.

Dear Sir,—In my large acquaintance amongst my photographic brethren in the provinces, I know of none to whom the knowledge of mechanics and the use of tools would not only be desirable, but in many cases, is absolutely necessary. The making of frames and stretchers for pictures properly belongs to the art of carpentering, but, being a very light branch, can be easily carried on, and oftentimes with better success, by an amateur. Accidents will frequently happen to apparatus. Experiments may be required which would serve to improve the formation of some suitable appliances. In the Photographic News are often put forward ingenious contrivances, easily made by those who know how, but otherwise almost useless. I have often heard it said: "Oh! any common carpenter can do it." This is a fallacy; the hands of a common carpenter, from the coarseness of his work, become hard and bony, and his touch insensitive. He is as unfit to mend or make a delicate piece of photographic apparatus as a blacksmith would be to do the same by a watch. Seeing this, I have often regretted that none of your correspondents have offered to give a few familiar instructions in what may be termed photographic mechanics. I will, with your leave, do my best to supply this requirement, first promising that I do not write for the clever ones who know everything, and secondly I promise that I do not advise any one to undertake the making of articles that can be obtained in the trade properly manufactured. The use of a knowledge of mechanics to a photographer is, that he may be ready in contrivances when and where they may be required, no assistance being at hand.

A short time since, in the News, a very interesting paper was given upon glue and its uses; it being the article of all

THE BALLOT AT THE PHOTOGRAPHIC SOCIETY.

SIR,—The report of what Mr. Spiller said at the Photographic Society's meeting renders it necessary for me to say a few words.

When it was seen that I was proposed for President, a number of my friends wrote to me asking what I wished done, and, in many cases, enclosed me their ballot papers to fill in.

In all these cases I (as a point of honour) struck out my own name even as Vice-President. In this way I know that I deprived myself of such a number of votes as would have obtained for me the latter position.

This was the necessary sequence of Mr. Spiller having proposed me without my knowledge, and I regret having been proposed in opposition to Mr. Glaisher, for whom I have strong personal liking and esteem.—Yours, &c.,

H. STUART WORTLEY.

THE PHOTOGRAPHIC SOCIETY.

SIR,—I see that Mr. Verge alludes to a circular sent out to a number of the members who had not paid their subscriptions as "offensive," at the late meeting of the Society. I received one of these circulars (not having paid my subscription), and I at once complied with its request, and paid my subscription for this year. So far from thinking the circular "offensive," I think it very right and proper that all bona fide members should pay up their subscriptions for the year, before they are allowed to exercise any rights of membership.

This is an inflexible rule in all clubs and societies of gentlemen, and is most strictly enforced. How long would Mr. Verge and his brother dissenters like to exercise the rights of members without paying their fees? Is it one, two, or more years? I heard rumours when the Society was nearly broken up, that there were some members voting and speaking at meetings who had not paid up their subscriptions for several years. It is to be hoped this is not the case. If it is to be the rule in future, I believe the Society will not last much longer. Already their fate of other photographers (old members of the Society) is talked of. Let us institute a rule by which the advantage of the Society seems to rest with those "professional" photographers who do not even condescend to pay their annual guineas to its funds, but take care to advertise their establishments by getting the best places on the walls for their pictures at the annual exhibition.—I am, sir, faithfully yours,

FRANCIS W. TURTON, Commander, R.N.

Bedford, February 16th.
experiment mentioned, and, finally, I found I had 530 grains of nitro-glucose. The powdered and dried lump sugar used weighed one and a-half ounce, or 666 grains, the weight of nitro-glucose being 120 grains less. The loss in converting was equal to 18.3 per cent., leaving 81.7 per cent., as the percentage of nitro-glucose obtained.

This second batch, I believe, is very good. It dissolves readily in collodion, and also, but slowly, in methylated spirit. A few drops of this last solution put into water gives a fine white cloud, which is excessively slow at settling.

The next experiment I made was on the 7th January last. Three and a-half ounces of dried and powdered saltpetre were put into the jar. Upon this was poured four fluid ounces of sulphuric acid stirred well in, then the jar covered over with the glass plate, and surrounded with water in the large wash-hand basin as before. Temperature in the yard, 46° Fah. In about two hours another ounce of acid was added, as the mixture had become quite hard. Three and a-half ounces of dried sugar were then gradually stirred in. The sugar made the mixture stiffer at first, but heat began to be produced, which made it quite thin, and show a yellow colour. I could see that mischief was brewing, and in a few moments carbonisation began, accompanied by volumes of red nitrous acid gas, which drove me away, the result being a large quantity of black, spongy, wet carbon, as before. This was the third failure. In this experiment I had again been operating upon too much material for the size of the jar, and there was a great change of weather.

On the 28th January, for the sixth and last time of trying, I endeavoured to repeat the experiment made on the 33rd December, when I obtained 530 grains of nitro-glucose. The same quantities of materials were used, but the water rose on the thermometer being now at 52° Fah. instead of a keen frost. While the mixture of acid and saltpetre was cooking, rain fell, and I had to wait till it ceased. The mixture when cooled was only half solidified, and the sugar made it still thinner. I should have had the carbon process over again directly had I not at once brought up a force I had in ambush in the shape of a jug of cold water to quiet the rising tendency, and produce tranquility, &c. All was put to filter, and after washing and kneading in warm water next day, I found I had 4714 grains of nitro-glucose, being 1841 grains less than the original weight of sugar used. This gives 28.17 per cent. as the loss in converting, and leaves 71.83 per cent. of nitro-glucose obtained. This result is about ten per cent. worse than the other—still think, the higher temperatures and greater moisture of the weather. My appetite for making nitro-glucose is now satisfied. I set out to try whether saltpetre could be used instead of monohydrated nitric acid, and I have proved that it can; and that ordinary commercial sulphuric acid may be used in place of fuming sulphuric acid.

In the absence of a proper arrangement for carrying away the corrosive vapours it is not a pleasant process. You are liable to be "over-exposed" out of doors, and may get a chill which will affect your "tone;" then "over-fuming" is sure to happen, and you get "decidedly acid," so you must not begrudge a good washing. You had better not have your Sunday clothes on, or, when you think you are "well mounted" you may discover some "spots" which will be rather difficult to "stop out.”

---

**METEOROLOGICAL NOTES ON THE YEAR 1874**

**From the Register of William Hy. Watson.**

The monthly mean, maximum, and minimum temperatures observed at Braystones, near Whitehaven, during the year ending December 31st, 1874, have been as follows:—

**1874.**

In the whole year 72°78'5" 72°18'8" 50°38'1" 72°78'5" 72°18'8" 50°38'1"

The following table shows the number of fair days, the number of days on which more or less rain fell, the number of fair, clear, and sunny days, and the number of fair days gloomy:

<table>
<thead>
<tr>
<th>Year</th>
<th>Fair Days</th>
<th>Rainy Days</th>
<th>Fair, Clear, and Sunny Days</th>
<th>Fair but Gloomy</th>
</tr>
</thead>
<tbody>
<tr>
<td>1874</td>
<td>176</td>
<td>189</td>
<td>106</td>
<td>70</td>
</tr>
</tbody>
</table>

Thus, during the year 1874, there have been 18 more days on which rain fell than absolutely fair days; and of the total number of fair days, the clear and bright days preponderate by 36. On comparing the means of the observations, we find that the mean temperature of the mornings was exactly the same as that of the evenings. In April the temperature was unusually high for that month. The mean temperature of December was 2° below that of December 1870, which was the last frost we had of any moment, and 5°2° below the mean of the same month in the previous four years.

---

**Correspondence.**

**Dear Sir,—I think it would have been well if Mr. H. Baden Pritchard, before giving you his version of my remarks concerning the Exhibitions of 1873 and 1874 (made at the recent meeting of the Photographic Society), had taken the trouble to correct his own impressions by looking into the accounts published last year by himself. He will there find—**

1st. That the total cost of the Exhibition 1873 was £112 13s. 7d., and not £128, as he tells you in his letter.
2nd. That the admission fee and sale of catalogue realised £83 odd; and that £50 was received for special advertisements inserted in the catalogue.
3rd. The total amount taken was therefore £113, and not £130, as stated by Mr. Pritchard.

"quis custodiet ipsos custodes?"

I am, yours, etc.,

John Spiller.
PHOTOGRAPHIC NEWS.

FEBRUARY 19, 1875.

SCORIAC.—The irregular light patches in the prints enclosed are not negligible, as you say, but simply a fault of the negative, and these may have been produced in various ways. They appear to us very like the results produced by an uneven coating of collodion. If the collodion flow in an uneven way, leaves such quick ridges or patches, and makes the silver solution flowing unevenly over the surface will cause such patches in development. Sometimes a reflection of light shining on the plate, and also such cracks, will cause such effects. Sometimes the uneven flowing of the developer will produce such a result. The first cause we have mentioned is most likely, from the appearance of the patch, where it is most probable.

HYDRATE OF CHLORAL.—Dallastype is the name given by the inventor to a method of producing, by photography, blocks for surface printing in the ordinary typographic press. The method consists in treating the surface of the type with a water-soluble compound of copper, to which is added a mixture of hydrate of chloral, or of chloral hydrate, and of solutions of gum arabic, and of any other materials, to give the desired property to the surface of the type. The type is then printed with the ink received from the type, and the result is a printing which is said to be superior to that obtained by any other method. The method is said to be very economical, and to give a printing which is much superior to that obtained by any other method.

Correspondence.

[Column continues with various letters and articles of interest to photographers and the photographic trade.]

To Correspondents.

FARNBOROUGH LANE.—The phenomenon you describe is by no means uncommon; we have seen it many times. The dark colour being developed in the collodion was, as you conjecture, the result of the liberation of free iodine. This was due to some trace of acidity in the air. It is a well-known fact that when collodion is treated with a solution of an ordinary chemist's somewhat acid; and either kept in a photographer's establishment, in a bottle not quite full, and exposed to light, will frequently become acid. The change back again from dark red to a comparatively colourless state is, although by no means uncommon, not so certainly explained. We have often seen it, but never except methylated ether or methylated spirit was present; and the probable explanation is that an iodide of methyl is formed, taking up the free iodine liberated.

H. ROBERTS.—We cannot give you a full explanation, because we are not quite certain of all the steps in the alleged process, of which the paragraph in question was, you would seem to be aware, a brief summary extracted from another journal. It is very probable that "and" should be substituted for "or." You are aware that a wash of iodide of potassium will destroy the sensitiveness of an exposed plate, and that exposure to light is supposed, in some processes, to improve the plate after it has been made insensitive by an iodide. The special novelty consists, apparently, in final treatment with a solution of tannin, instead of a solution of silver. Dr. Vogel has proved that tannin acts as a sensitizer to iodide of silver. Of course, after the plate has been treated with the tannin, it will require the same care to protect it from light as an ordinary plate rendered sensitive in the silver bath.

E. DODSON.—You are still scarcely sufficiently explicit as to the character of the photographs you possess, and the mode of exhibiting them which you wish to try. Are they transparent, and do you wish to exhibit enlarged images of them on a screen by the aid of the magic lantern? Or are they paper prints, and, by using them for a "peep-show," do you mean to enclose them in a box with a good light upon them, and exhibit them through a large lens? In either case you will be able to obtain the requisite apparatus through some dealer in photographic instruments.

See second page of our advertising sheet. 2. The collection which is too thick may be diluted either with new thin collodion, or with equal parts of ether and alcohol.

P. A.—A quarter-plate portrait lens will answer well. As a rule, the focus of the condenser should be about twice its diameter.

NORMAN MAY.—The use of permanent plates for intensifying carbon prints or negatives was indicated by Mr. Swan some years ago. We will, however, at an early date refer the communication, and furnish you with details. Many oaks.

ALEX CHARDON.—The use of permanent plates for intensifying carbon prints or negatives was indicated by Mr. Swan some years ago. We will, however, at an early date refer the communication, and furnish you with details. Many oaks.

A YOUNG PHOTOGRAPHER.—We have, in the volumes of the PHOTOGRAPHIC NEWS and in the Year-Book, already published given very many articles on the production of transparencies for typographic printing. We have also published practical articles on the usual practice of the art in all departments, the primary object of a journal is to give a record of the progress of photography, its discoveries, modifications, and improvements, rather than to repeat known processes, which we have already published. If you have our back volumes, you will, on reference to the indexes, find many articles on the subject of your enquiry. We do not remember that the gentleman to whom you refer has published any details of the process he works. Professional men working a specialty often feel inclined to enter into such detail. If you will tell us the methods you have tried, and any special difficulties you have encountered, we can probably help you. In the meantime, we will boar in mind your wish, and when opportunity serves give a resume of the most approved practice.

A BOUGHER.—Many thanks.

AN OLD MEMBER.—We cannot give any precise information on the subject, and it is not wise to discuss it on conjectural information. You will probably obtain the information on enquiry at the meeting. We understand that some voting papers were rejected, and that the ground work was no worse than the one that was referred to, by the owner's wish, not nominated for the council. Is it not well, for the Society's sake, to let the whole matter rest?

ERRATA.—In our list of officers of the Photographic Society the name of Mr. H. E. Bould was seen in error. It should have stood fourth in the list of the council. In the letter of Mr. C. Ferranti, published a fortnight ago, on "Life-size Portraiture," first line of second column, page 70, for a deal of great satisfaction, read "debt of gratitude," and in last line of second paragraph of the same column, for "make the attempt" read "made the attempt."

Several Correspondents in our next.
The Photographic News, February 26, 1875.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

DIFFICULTIES IN PORTRAIT PHOTOGRAPHY—The East Indian Eclipse Expedition and Dr. Vogel—Action of Light on Aniline Colours.

Difficulties in Portrait Photography.—Some years ago there were many things inveighed against by portrait photographers, who knew they could never produce satisfactory results for their sitters if the latter came dressed in garments unfavourable to photography. Blue dresses, for instance, were disliked, because they came out light; and white ones, because they came out dark. Black and grey, or generally, any shade of black, were considered safe for the sitter. But should any individual have worn an apple green, or grey, or anything in between, the photographers would have had their hands full, and the result would have been a failure. This, however, is no longer the case. It is now found that, with the new lamps of electric light, and other more efficient illuminating apparatus, all sorts of dresses can be photographed without serious inconvenience.

Action of Light on Aniline Colours.—M. Borlinetto, in the Révue des deux mondes, has given an account of some experiments he has been making to test the sensitiveness to light of aniline colours. He mixed them with various substances, such as starch, gelatine, and albumen—or, rather, spread the pigments upon papers prepared with these materials. He found that Hofmann's blue changed its colour quickest upon starch-paper, and more slowly upon the sized and albumenized papers. But if the solutions be applied to cloth and left to dry, they remain perfectly original. The result is that of a mixture which, although not so sensitive as the pigments, is very sensitive, and may be used in photography without any inconvenience.

The result is that of a mixture which, although not so sensitive as the pigments, is very sensitive, and may be used in photography without any inconvenience.

The East Indian Eclipse and Dr. Vogel.—Our readers will be glad to learn that our friend Dr. Vogel, of Berlin, will take part in the British eclipse expedition, which is now on its way to Singapore. The Royal Society issued invitations to three foreign gentlemen to take part in the observations; Dr. Vogel will represent Germany; M. Janssen goes on behalf of France; and Prof. Tacchini will be the Italian assign chosen. The main object to be secured will be a photograph, or rather a series of photographs, of the spectrum of the sun's corona. The whole expedition is under the charge of Dr. Schuster, who sailed ten days ago for the East. M. Janssen is already at Singapore, awaiting the arrival of the expedition.
FRENCH CORRESPONDENCE.

PHOTOGRAPHY AND OCEANIC STORMS.—A FRENCH MANUAL ON CARBON PRINTING—PREPARATION OF THE PIGMENTS—PORTRAITS IN CARBON—SULPHOCYANIDE OF AMMONIUM FOR PRINTING.

Photography, which has rendered such important services to astronomy on the occasion of the transit of Venus, may certainly find other similar applications in the domain of science. Thus the different theories which have been advanced hitherto touching the movement of a ship upon a stormy sea has only been of an approximate character. Photography offers the means of registering with mathematical accuracy the successive inclinations impressed by the billows, and in this way it would be possible to learn something of the law that governs the movements of the ocean. Some curious experiments, the results of which have been communicated to the Academy of Sciences, have been made at Brest by an officer of the French navy. I need not enter into the description of the process employed, because it would lead into too abstruse matters; but I will say that the impressions exhibited to the Academy have excited a most lively interest, and appear to be of a most conclusive character.

One of the veteran photographers in pigments—M. Boivin, of Marseilles—has sent me the manuscript of a very complete manual of this method of printing, which, as I mentioned in my last letter, has at last obtained a firm footing among the professional photographers of France; this work is the fruit of several years' study and observation, controlled by experience.

The teachings that the author draws from his long practical studies are the following:—The sensitizing of the paper should be done in a solution of bichromate of potassium which is kept in a closed vessel; the fixing and washing taking place in a croyderol bath. The drying of the tissue should be conducted in a warm and airy apartment. The solubility of the pigmented paper should be ascertained before placing it under the cliché. The tissue requires to be printed with accuracy, as determined by the aid of a photometer. The washing of the pigmented paper after printing should be as rapid as possible, and the contact between it and the transfer paper must be as perfect as possible. The plate must be developed in water, which should not be too warm, and ought to be filtered if necessary. The fixing takes place in a solution of alum, of three or four per cent.

As to the failures which may be encountered in the process, M. Boivin resumes as follows:—Where the contact between the paper and the print is imperfect, the transparency of the half-tones is lost, and one is liable to partial lighting of the film. The operator should take heed not to change the temperature of the water too suddenly which is used for development. Filtered rain water is best to use for the purpose. An image rendered yellow by the bichromate may be made white again by passing it into a two per cent. bath of cyanide of potassium. If the exposure has been too short, the half-tones are wanting; if it has been too long, the other hand, the impression is thickened, and refuses to develop.

The preparation of the colouring mixture which compose the pigmented tissue is one of the most important points in the process, and M. Boivin makes, in reference to this, the following observations:—In preparing black tissue, employment can be made of lamp-black, which as may be obtained in commerce, well purified, and finely ground. It is mixed in a mortar with glycerine and a trace of phenic acid, and in this state it will be found to keep perfectly. If ordinary soot is to be used, it is necessary in the first instance to separate the grease from it, and this is done by washing it in benzole, and then in potash, ammonia, and water. For carmine black (a tone which comes very close to the tint of ordinary photographs) refined lampblack is taken, and to it are added a few drops of an ammonical solution of carmine. Such pigments as red chalk, and the like, are prepared by washing and levigation so that an impalpable powder is secured.

The pigments are put into a fine linen cloth, of which a bag is made by tying the edges together, and plunged into warm water in the same way as if you were using a stick of Indian ink. When the water is very much charged with colouring matter, it is poured into a glass vessel, and the operation is continued until the pigment has all gone. After having allowed the liquid to stand for some time, so that the coarser particles have had time to settle, two or three times, the solution is extracted of the precipitate, which is afterwards obtained from this serves as a pigment for the tissue. It is preserved with glycerin and a trace of phenic acid, in the same way as the lamp black. If it is desired to employ sepia, in order to render it without any action upon gelatine, it is boiled first of all with a saturated solution of bichromate of ammonium, and then thrown upon a filter, and, by means of ordinary water, the precipitate is washed repeatedly, and is then ready for use. Thus prepared, the sepia employed in the preparation of the pigmented tissue has not the inconveniences of sepia in its natural state, which renders gelatine perfectly insoluble in a very little while. As to plumbago, which is employed in certain instances, this is reduced to an impalpable powder in the mortar, and is then diluted with water, which is evaporated by placing the mixture in a water bath, from which prints produced with plumbago resemble very much drawings in crayon, and are of a very artistic nature.

One of the most interesting sections of M. Boivin's work is that concerning the production of a print in its true sense by double transfer. He assures us that the operation may be easily performed as follows:—After having well cleaned a plate, it is rubbed with a flannel dampened with a solution of a little carbon tetrachloride or petroleum oil is adherent. After having allowed the solvent to evaporate, which takes place in a few minutes, the glass plate is rubbed uniformly with a very dry flannel, so that no very large amount of wax remains on its surface. The plate is preserved in this state, and when required for use the surface is coated with old collodion that has been rendered very fluid by the addition of alcohol and ether. The plates are then plunged into a water bath, where they remain whilst the printed tissue is being washed in another vessel; then the tissue is placed upon the film of collodion and withdrawn from the bath, and, having passed the squeegee over the image to ensure perfect contact, the same is allowed to dry spontaneously. After destillation it is merely necessary to lift the print in order to uncover the negative. The production of a solution of wax, of which mention has been made, M. Boivin employs very successfully castor oil, or even stearine dissolved in alcohol; all these materials give identical results. This process of double transfer furnishes prints which rival the best that can be obtained with silver printing. Thus M. Boivin observes they are at once in their proper condition, and glazed; the method therefore is especially suitable for cartes-de-visite and portraits of this nature. In the reproduction of engravings in which a fine matt tone is desired, no collodion or gelatine should be used; in this case it is preferable to employ paper as the definite basis—gelatino-alum paper, for instance.
that gentleman has written me a few lines on the subject which it will be useful to all to know. M. Meynier, as a manufacturing chemist, produces the salt at two francs and a half per kilogramme, and at this price it is sold wholesale to chemists, who retail it again at about six or eight francs. This is a fact which has an interest for every photographer. The agent in Paris, it appears, contents himself with a profit of half a franc only per kilo, and if all chemists were to do the same, it is certain that sulphocyanide would be generally used for fixing; and a great demand for the material would arise, so that vendors would soon recoup themselves for any abatement they might make in the price now charged for the product.

Ernest Lacan.

THE PRACTICAL Printer IN AMERICA.

XVIII.

"A Few More Remarks about Printing—Treatment of Broken Negatives.

"In my chapter on The Positive Bath for Albumenized Paper, I have given a variety of formulas for both preparing and taking care of the printing-baths, which I have either by my own, or by the experience of some photographic friend, proved to be very fine in their results, if carefully put into practice, as is recommended.

"When some samples of paper are floated upon the silver bath, a treatment is required which at first seems peculiar. If you float this paper upon a medium-strong silver bath (40 to 45 grains strong in summer), it will have to be floated a long time to obtain good results, and if floated upon a weak silver bath (35 to 40 grains strong, also in summer) it will have to be floated a short time. The reason of this is obvious. A strong silver bath repels the paper at first for quite a number of seconds, and if removed from the bath before the paper has taken to it, it will dry in tears-drops, and when printed it will be marbled in its looks, which is in itself a sure sign of too short silvering. If the paper when removed from the bath curls considerably, then that is another sign of too short silvering, and, consequently, paper silvered on a strong silver bath should be silvered for a longer time than what you would silver the same on a weak bath, and then the paper will have a strong solution on it, and will be very brilliant, both when just removed from the printing-frame and when dried and finished; but it will be much more bronzed in the shadows. For weak or flat negatives that paper would be useful, but for more strong, i.e., neither weak nor weak negatives— it would not, and for the intense negatives it would be sadly out of place.

"For medium negatives, the bath for sensitizing the paper should be from 28 to 33 grains strong, of silver alone, to the ounce of water during the summer; and while you float in the former case on a bath of 46 grains, from thirty-five to forty seconds, you should not in this case float more than from twenty to twenty-five seconds. If you float some samples of paper on a 50 to 33-grain bath longer than twenty-five seconds the paper will print 'woolly,' even if silvered only five seconds more than the allotted time. The paper is easily told as to whether it will print woolly or not by examining the surface of the freshly silvered sheet as soon as it is removed from the bath; if it looks dead and suntanned you may be assured that it will look exactly so when it is printed. The experienced printer, when he removes the first sheet of paper from the bath, can tell whether he is silvering the right time or not (at least, very nearly), and then he can act accordingly, with astonishing accuracy.

"There are often very bad results occasioned by having the silver solution too cold. This is especially the case in the winter. Look out for it, if you wish to avoid it, both in the sensitizing and working of the paper. During the hot months of summer the paper should be kept in a damp box for a day or so before it is silvered, for when the albumen on the paper is in a damp state it will more readily take to the bath than when it is dry and horny. During the winter the paper should not be kept in a hot room, for the same reason. "Treatment of Broken Negatives.—In many cases, a negative that has been broken can be mended so as to be strong enough to resist all ordinary pressure of the back-board while printing, providing another glass is first laid in the frame and the negative laid on it. "Lay a piece of cotton flannel on a level bench or table where there is plenty of light, and match the broken pieces of the negative on it, face up. Examine the pieces closely with a magnifying glass, and lay them in exactly the position they were in before the negative was broken. Now cut strips of plain unsalted paper, about an inch wide—no more, though—and apply melted glue to one side of them; now place the same side of the paper to the borders of the negative, permitting about half an inch of the width to project out beyond the glass. Do this to all of the sides, and then turn them over the edge—i.e., the thickness of the glass—on the varnished side of the negative and rub the paper with a tuft of cotton to make it stick. The negative, as it is now, has a half-inch strip of paper glued to the four sides of the varnished side of it, and also a half-inch strip projecting out beyond the edges of the negative, which has glue on it, but is not as yet stuck to the other side (Fig. 1). When the paper is dry, turn this negative over and apply moisture to the glue on the paper, and draw it tightly, yet tenderly, over the edges of the glass, and press it down smoothly on the back of the negative. Do this in turn to all the sides, and then, when the paper is dry, you will find the pieces quite strongly held together, and you can move it about in and out of the frame, without any danger of the pieces separating. "But, however, if those strips of paper do not hold the negative sufficiently together, as in some cases they will not, then lay the negative, face up, on a piece of plain unsalted paper, match it, and with a knife or shears cut the paper around the negative, leaving sufficient of it on all sides to allow it to turn over, not too far, on the varnished side, which you remember is uppermost (Fig. 2). Mark with a lead-pencil on the paper on all sides of the negative, close to the edge of the paper. Now remove the negative and apply glue to the side of the paper which has been marked. Apply evenly, and lay the pieces of the negative quickly on in their proper position, before the glue has commenced to dry. Bear in mind that the glass or back part of the negative is laid down on the glued paper, and see also that the negative when placed together lies on the paper as it did before you removed it to glue the paper, which position is easily told by the marked lines on the frame. "When the pieces are matched exactly by the aid of a magnifying glass, then gently draw the paper up which projects out beyond the sides of the negative, and stick them to the varnished side of the glass. This paper should not cover so much of the varnished side as to cover any part of the negative that is to come in the print when it is finished. The negative should then be turned over, which can very well be done if you were, in the first place, to place under both paper and negative a whole glass of the same size, or a little larger if desired, as the mended
negative would measure. By taking hold of this under glass, and placing a couple of fingers on the broken negative to prevent it from slipping, you can easily turn it over, and then lay it on a level state covered with soft flannel. First, blow a tube upon the paper which is stuck on the back of the negative, commencing at the middle and rubbing outwards, so as to secure both perfect contact and for the purpose of removing air-bubbles between the two surfaces. Let dry, and you will have a negative that can be printed, if you wish, without another glass being placed first in the frame, and which can now be used.

"This negative having a thick white paper on the back of it, will necessarily print slowly, but if printed face up to the strongest sunlight, but little difference in the time of printing will be noticed. Medallions or plain prints can best be made from such a negative, though it may be vignetted by placing a Wasmuth vignette-paper on the back of it. The contraction while drying of the expanded paper will draw the pieces of the negative more firmly together, and thus secure greater exactness."  

THE CAUSE OF SOLAR HEAT.

BY DAVID WINTSTANLEY.*

When a body possessing the visible energy of mechanical translation is arrested in its course, that energy, according to the laws of conservation, is not destroyed, but becomes apparent in another form, generally in the form of heat. Should a body receive two equal impulses in diametrically opposite directions at the same time, mechanical translation as a result thereof is impossible, and the energy thus expended, it appears to be agreed, will in the main assume the form of heat. Should a body, however, receive two equal impulses in directions inclined to each other, mechanical translation will ensue, but the value of the energy of visible motion thus communicated to the body in question is not equal to the sum of the impulses, being, as is well known, justly represented by the diagonal of a parallelogram the length of whose sides is proportioned to the value of the primal impulses. What, then, in this case, becomes of the residue of energy applied, and not converted into visible motion? I apprehend it assumes the form of heat. If so, in the instance of a body receiving equal impulses in directions inclined to each other at an angle of 120°, the resulting visible motion will just account for the energy of one of these impulses, and the resulting heat for the energy of the other; and then, a body being a certain visible energy observable as rectilinear movement have a series of impulses imparted at an angle of 120° in each instance to the line of motion, and equal in value to the visible energy of the body at the time of application, the body in question will gain nothing in visible motion through the application of these impulses, but will simply alter the direction of its movement at each application, and heat at the same time an amount of heat of which the impulses is the mechanical equivalent. Adopting this view, it matters not at what angle the impulse may be given, for so long as the figure representing its amount yields with that representing the visible motion of our body a parallelogram whose resultant is equal to the line of visible motion, it follows that the energy of mechanical translation remains unaltered, and the energy of visible motion transformed into heat. This condition of things, however, is what obtains in the instance of a body in planetary revolution in a circular orbit. It is continually receiving impulses through the instrumentality of gravitation at or nearly at right angles to its line of flight, and its energy of visible motion does not increase, whence I infer that the mechanical energy by which its rectilinear movements are destroyed is converted into an equivalent of heat which elevates the temperature of the planet so far as its conditions of radiation will permit. The aggregate value of the impulses required to make a body describe a circle and return to its starting point, and derive the principal and direct gain of visible energy, I have endeavoured to determine graphically by means of the mechanical parallelogram. The result at which I arrive is, that the aggregate in question exceeds the momentum of the body to be deviated in the same proportion as the circumference of a circle exceeds its radius, and this irrespective of the circle's size. I have not attempted to calculate, nor attempted to deduce, what fraction of the matter of the earth would be elevated by a sudden stoppage in its orbital path, for it appears to me that satisfactory data for doing this do not exist. The number of thermal units to which such a stoppage would give rise if multiplied by 6.28 indicate the amount of heat which, upon the present hypothesis, the earth annually receives through the instrumentality of solar gravitation. This amount will, I apprehend, amply account for a certain initial temperature of the terrestrial matter, and for that excess of internal heat which appears to have been pretty well made out. It will be evident that any heat which, in virtue of this hypothesis, may be supposed to fall to the lot of our earth, will, in some calculable proportion, fall to the lot of the other planets also. The assumption that the planet's mass multiplied into its velocity in orbit, and divided by its periodic time. Of course this amount of heat will be distributed over the entire matter of the planet, the temperature of which will depend on the capacity for heat of the matter composing it, and on its facilities for radiation. These latter will clearly diminish with the comparative diminution of superheating, and, in a great part, by the larger extent of their atmospheres. In the case of bodies moving in elliptic orbits, the amount of energy which, according to this hypothesis, will be transformed to heat in a single revolution will be practically as before; i.e., 6.28 times the planet's visible energy of motion at its mean distance from the sun. There will, however, be this difference between the two cases: in the instance of a body moving in a circular orbit, the ascension of heat will be a constant quantity in equal increments of time and in all parts of the orbit, whereas in the case of a body moving in an ellipse, the ascension will be least in approaching the perihelion, and greatest in receding from it, inasmuch as the solar gravitation produces an increase of mechanical translation in the former instance, and diminishes it in the latter. Assuming the theory to be correct, this circumstance is one which will greatly mitigate the extremes of heat to which, apart from such a consideration, we should expect cometic bodies to be subject. Indeed, in spite of the enormous distances to which they recede from the sun, the voluminous nature of their atmospheres, by which radiation must be diminished, may, in conjunction with this view of the case, afford an explanation of the unexpectedly high temperature which, in the case of these bodies, the spectroscope certainly seems to indicate.

The application of the views herein advanced to an explanation of the cause of solar heat is briefly this:—As the mutual and ever-acting gravitation of the sun and his attendant planets produces in the instance of the central luminary no more acceleration of visible motion than in the instance of the planets themselves, the gravitation must result in the exhibition of some other form of energy, which, in the one case as in the other, will, I apprehend, be the form of heat. Carrying, however, this idea to the extreme, we should be led to infer that the force of gravitation, which in some circumstances is certainly capable of transference into the form of mechanical translation, and thence into the form of heat, is in others just as capable of transference into the form of light. Whatever this may be, it is to be regarded as the individual movement of a multitude of particles whose simultaneous movement is observable as mechanical translation, it is but reasonable to suppose that

A force acting upon all, but, from the circumstances of the case, incapable of producing a simultaneous and concordant movement, will produce an individual, and in a sense discordant, motion of those same particles. Looking at the matter in this way, any agglomeration of particles whatever must have some initial heat as a result of that gathering. The present consists of little quanta or molecular units as elements of translation. And as in our experience gravity is unceasing, this heat, so far as we can see, should be never ending during the continuance of those conditions which prevent the movement of translation; and a never-ending supply of heat must cause an elevation of temperature which will only cease when a point is reached at which the rapidity of radiation equals the rapidity of supply. The more numerous the particles comprising the agglomerated body, the less become the opportunities of radiation, and the more elevated the temperature, which latter attains its maximum in our own system in the instance of the suspended body which maintains the superficial mundane heat by irradiation from its fires.

It will be seen that the theory here projected places itself in accordance with the doctrine that "a stone high up" has anything which can justly termed "the energy of position." But I have already occupied sufficient time without staying now to combat further the doctrine I have named.

To those who have been accustomed to regard gravitation as a property which enables bodies to act where they are not, the present consideration will present itself as mechanical not encountered by others who accept the beautiful, and to my thinking more rational, hypothesis that the simple mechanical movement of infinitesimal particles is the immediate cause of that grand effect, the law of universal gravitation.

ON THE CAUSE OF DEPOSITS OF SILVER UPON WET COLLODION.

By G. Vander Mersbrugge.

I have been giving some attention to the subject of irregular deposits of silver which are very often seen upon wet collodion plates during development. In order to explain clearly the remarks I have to make on the subject, I may state, first of all, that every liquid possesses at its surface a tension or contractile force of its own, which diminishes as the temperature becomes more elevated. For this reason the same phenomenon take place as if there was a skin or membrane stretched evenly over the surface, supposing the temperature to be uniform, the tension being greatest where the temperature is lowest. It follows from this, that if we suppose a superficial film of a liquid, without weight, non-adherent to a solid body, and perfectly free to obey the interior forces that exist, this film will contract at once, and assume a spherical shape, corresponding to the least possible surface for any given volume. Weight alters more or less, but does not destroy this construction, as proved by the spherical form of rain, soap-bubbles, &c.

The fresh surface of distilled water at a temperature of 15° Cent. possesses a tension or contractile force about equal to 7-5 milligrammes per millimetre of length, while the tension of ether, at the same temperature, is only 1-9 milligrammes, and that of alcohol 2-5 milligrammes. It follows, therefore, that if we plunge a plate of glass into distilled water, and then withdraw it with a pair of perfectly clean pincers, and deposit upon the film of water adhering to the surface of the plate a drop of alcohol or ether, the plate being held horizontally while the tension of water, being much stronger than that of the ether or alcohol, will produce a rapid spreading of the drop, and the liquid film will thus possess thickness of a very different nature at different places over the surface of the plate. The same phenomenon takes place when distilled water is substituted for a solution of silver.

It is clear, after these experiments, which are easy of repetition, that if the liquid film covering the plate, after it has been withdrawn from the silver bath, contains here and there little quanta of the solution, the necessarily produced phenomena of dilation at those places where ether and alcohol are to be found. Therefore the film will be more or less unequally distributed, and the chemical actions developed by the luminous rays will themselves be very irregular at certain points.

As soon as the quantity of ether and alcohol mixed in the plate becomes large enough to resist the force of the plate may contain these liquids in every part, and then the phenomena of dilation are less pronounced, or even still, provided the evaporation of the plate is the same throughout. Now this last condition of things is very difficult to realise, and thus the warmest portions are more or less attracted towards the colder places.

In general, it is necessary, in order to obtain a regular distribution of the liquid film covering the plate, not to place it in contact with any body of a greasy nature, nor to touch it even with the fingers, for there always become detached little particles of grease, which, although invisible, are quite sufficient to dilate the liquid on the plate by reason of its weak superficial tension.

To render this more intelligible, I may quote the following experiment. Into a glass dish, filled with a scrupulous care, there is poured some distilled water, and upon the surface of this is deposited a few small pieces of camphor, not more than one millimetre in size. They will be found to begin to turn rapidly, moving about with extreme vivacity; these movements are due to the fact that there separate from the surface of camphor in contact with the water a very minute current of essential oil, much less contractile force than water; and as this oil does not detach itself equally all over the surface of the atom in contact with the superficial film of water, it moves about with unequal force. If we plunge a finger into distilled water, every movement of these particles ceases as if by magic. This is because invisible greasy matter has become detached from the finger, and has diminished too sensibly the tension of the liquid to permit of the particles of camphor being set in motion.

These experiments demonstrate, I think, the necessity of some precautions to prevent deposits of silver of irregular character from taking place during development.

1. To attenuate the differences of tension of ether, alcohol, and the silver plate, by adding any insensitive substance to the latter, and to lower the tension of nitrate of silver. The addition of camphor to the silver bath is said to prevent the blistering of paper sensitized upon it; perhaps this remedy acts from an analogous reason.

2. To render as short as possible the differences in temperature of different portions of the sensitive collodion plate, for the tension diminishes as the temperature augments, and thus the fluid portions are drawn towards the coldest. This remark seems to me to give the key to many failures with which photographers are afflicted during very hot and very cold weather.

In conclusion, I will mention a substance which acts like camphor, and which will thus be of assistance to operators in preventing irregularities in the thickness of liquids. I refer to saponine. A very weak solution of this (0-01 per cent., for instance) possesses the singular property, discovered by M. Plateau, to oppose great resistance to every displacement of surface, or, in other words, it enjoys very great superficial viscosity; I believe further, that it is inert, and, therefore, the addition of it in minute quantities to a liquid might be advantageous.

Should the preceding conjectures be borne out by experience, the theory of the superficial tension of liquids will be of undisputed significance in photography.

"REMBRANDT" AND OTHER EFFECTS IN PHOTOGRAPHIC PORTRAITURE.

We always regard with pleasure, as a healthy and satisfactory symptom, the reading of papers on the artistic side of photography before societies. Three such papers, each containing much both of interest and of valuable practical suggestion, have been recently read: one before the South London, and two before the London and Birmingham. It has been often remarked that of pictorial art, as of poetry, the faculty must be in-born, as no study, no training, without the natural instinct, would ever make an artist. Ruskin suggests that mere painstaking is valueless without something much higher, when he remarks that "patience and sand-paper will not make a picture." All fine art and painting, in reality and higher qualities of art, and true enough in relation to the highest qualities possible in photography. No study, no training, would have made a Rejlander, his work distinctly being the produce of a creative faculty. But an artistic instinct may lie dormant, and require educating and developing. Interest in good art, and familiarity with the best examples, have a wonderfully educating influence. Knowledge of what constitutes good art is one of the most important elements in the education of the artist, and that is a thing which can, to a considerable extent, be acquired by study. Hence the reading of papers on such subjects, and their consideration and discussion, cannot fail to have a valuable influence in raising the general standard of amateur photographers. It is very important, however, to avoid error as far as possible in such papers and such discussions, and in proportion to the excellence and weight of the dicta becomes the danger of error, as the error may easily gain the authoritative weight of truth from being found in its company.

The immediate purpose of our reference here is to call attention to certain allusions which occur in each of the papers to which we have just referred, and to some of the discussions which followed. It has often been the custom of late to refer with considerable disparagement to a style of portraiture which has acquired very much vogue during the last few years, and which is distinguished by the name of "Rembrandt." The name is probably foolish enough, insomuch as it provokes comparison which must of necessity be with Rembrandt. The intention, however, in adopting the designation is plain enough. The general custom in photographic portraiture, which prevailed for many years, was to flood the sitter with so much light as could possibly be used with any chance of securing fairly rendered contours and some degree of relief. In what is termed the "Rembrandt" portrait the avowed aim is to secure a similar prevalence of shadow and half shadow to that which characterized the works of the great master of chiaroscuro; and the mode of securing this effect was—to compare great things with small—not unlike that used by the painter; in both cases the sitter being illuminated by light from a narrow, concentrated source. But passing by the somewhat unwisely ambitious name, let us glance for a moment at the thing. In doing this, let it be understood that we do not take the failure in type more than we condemn a system because of its abuse. The black faces, with a streak of light indicating the outline of a nose, are really travesties of the style. He who imitates a style because it is in fashion (not because he appreciates it, or comprehends its intention) generally burlesques it unconsciously, by exaggerating the obvious characteristics and overlooking the subtle beauties. It is by far more intelligently produced excellence the same degree of success would be judged. To avoid invidious reference, we may refer to the "Rembrandts" of such men as Kurz and Napoleon Sarony, of New York, and Lockhardt, of Vienna, as examples of what we mean.

But in order to estimate the style rightly, it should be borne in mind that it existed long before the questionable name was applied to it, and its greatest master, if not its originator, was O. G. Rejlander. In his compositions, and pictorial studies especially, and frequently in portraiture, he delighted in rendering the bulk of the picture (often including the face) in half shadow, with the smallest possible touch of pure direct light to complete the scale of tones. Mr. Robinson has, from the time of his earliest known photography, been a master of the art of Edinburgh portraiture. The degree of the effect produced by faces in shadow, which are illuminated by a single touch of sunshine. It is only of late years that the system of producing faces in mezzotint instead of full light has been conventionalized, and, being adopted by some photographers of no artistic culture, the results have at times been offensive just in proportion to the ambition of the attempt. But to the photographer who knows his art, the highest mark of the highest degree of producing pictures of this kind is a valuable education, which he would never have attained by remaining in the commonplace groove to which so much of photographic portraiture has belonged. Mastery over lighting is the most important element in the culture of a photographic portraitist; and judgment in applying the various possible lights is the test of the best individual result, and avoid general monotonv in his work, is of no less importance.

A curious error or misconception appears in one of the discussions at the Edinburgh Society, if we read the report correctly. It was objected that certain effects, in the nature of reflected lights—or, as it is phrased in the report, "effects produced by "false reflected light"—were thoroughly untrue to nature. Surely this is a curiously misleading statement. What, it may be asked, is the direct light or the reflected light which alone is true to nature? Every light in which a person may by any chance be placed in, its degree, true enough to nature. It may be unusual, and hence give the person an unusual, and, by latitude of expression, an unnatural, appearance; but in unusual lighting the question of the aim must be considered, whether it is to secure a pictorial or realistic effect. If unusual lighting is to be condemned as unnatural, the glorious lighting of Rembrandt must fall under that condemnation, inasmuch as the concentrated light coming through a small high window of a mill—the typical lighting of the master in question—could scarcely be considered either usual or natural. The most usual, whistling it to secure the sitter to that secured by the narrow side light of a window in an ordinary room, and this would probably most nearly approximate to the lighting adopted in producing the mass of the so-called "Rembrandts." But if it is difficult to affirm that any form of direct lighting is really unnatural, how much more so it is to decide what reflected lights are unnatural or
false? The skilful rendering of reflected lights is one of the greatest charms of pictorial art, and the glorious quality of Rembrandt's work is very much due to them. The mass of most of his pictures is in shadow, but these shadows glow, reflected lights carrying the eye into the deepest gloom. The reflected lights on a figure are produced in degrees by every object around it, and are perpetually changing. The only really false reflected light is that which has been heightened in a photograph by combination printing, in which figures are printed side by side which, not having been produced side by side in the camera, have not, and cannot have, that effect of truth which would have been produced if the minor reflections produced by each on each had been present. Reflected lights being so numerous and varied, there is not much risk of their present being forgotten. The really great drawback we have noticed in many of the "Rembrandts" has been the absence of sufficient reflected lights to make the masses of shadow luminous. The effect of transparency in shadow is only secured by the presence of detail, and this can only be rendered in the shadow by reflected lights; and it is because the crying sin of photography is its want of this characteristic style in particular, is the want of the multitude of reflected lights which give the artificial and real pictorial value to the presentment, and because of the far too common presence of black, opaque shadows, that we call special attention to what appears a dangerous misconception. The use of reflecting screens undoubtedly requires judgment, as it is possible to give flatness rather than aid in the effect of roundness and relief, by producing a false reflection; but judiciously used, we feel assured they may be very valuable, and produce effects neither false nor unnatural.

We so cordially agree with the condemnation which is applied to the excessive retouching by which the effect of stone is substituted for the texture of flesh, and by which all anatomy is worked out of the face, that we are scarcely inclined to express the general truth of life, ameliorates the exaggerated rendering of features, nose-mark, red hair, &c., to which photography so often does less than justice, will always find his art popular. Let it also be remembered that Rejlander, whose aim was to make his art true more than popular, and who is often cited against retouching, was really one of the earliest who applied artistic manipulation to supplement the shortcomings of photography. The modern system of working all the out of a negative he utterly condemned; but no one was his superior in manipulating a negative to improve its pictorial value, by masking, subduing, and combining; and further, by using a pencil of light by which he could literally work as with a crayon on a print which he deemed needed treatment. He felt that appliances of this kind were legitimate enough for a dark and careful character, but that to abandon such aids, in his strong disgust of the falsehood which the modern mode of tampering with negatives had introduced into what he regarded as the art of truth.

A NEW PHOTOGRAPHIC PAPER—BROMIDE OF SILVER FOR PRINTING.

PROF. SCHULTZ-SELLAC communicates to the Mittheilungen a very interesting and important article on the use of bromides in albuminized paper, either wholly or in part, as substitutes for chlorides. He says:—

"The chemico-photographic printing process involves the employment of chloride of silver. The principle, known since the commencement of the century, that paper impregnated with chloride of silver, especially in the presence of an excess of nitrate of silver, becomes darkened by light, first attracted attention on the publication of Talbot's experiments, which were made known at the same time as Daguerre's great discovery. Afterwards the coarser paper surface was replaced by albumen, starch, or collodion films, the colouring in this way being rendered more lively, as in the case of a printing under a varnished surface. Fuming with ammonia has been the most important improvement in this method, by combination printing, in which figures are printed side by side which, not having been produced side by side in the camera, have not, and cannot have, that effect of truth which would have been produced if the minor reflections produced by each on each had been present. Reflected lights being so numerous and varied, there is not much risk of their present being forgotten. The really great drawback we have noticed in many of the "Rembrandts" has been the absence of sufficient reflected lights to make the masses of shadow luminous. The effect of transparency in shadow is only secured by the presence of detail, and this can only be rendered in the shadow by reflected lights; and it is because the crying sin of photography is its want of this characteristic style in particular, is the want of the multitude of reflected lights which give the artificial and real pictorial value to the presentment, and because of the far too common presence of black, opaque shadows, that we call special attention to what appears a dangerous misconception. The use of reflecting screens undoubtedly requires judgment, as it is possible to give flatness rather than aid in the effect of roundness and relief, by producing a false reflection; but judiciously used, we feel assured they may be very valuable, and produce effects neither false nor unnatural.

We so cordially agree with the condemnation which is applied to the excessive retouching by which the effect of stone is substituted for the texture of flesh, and by which all anatomy is worked out of the face, that we are scarcely inclined to express the general truth of life, ameliorates the exaggerated rendering of features, nose-mark, red hair, &c., to which photography so often does less than justice, will always find his art popular. Let it also be remembered that Rejlander, whose aim was to make his art true more than popular, and who is often cited against retouching, was really one of the earliest who applied artistic manipulation to supplement the shortcomings of photography. The modern system of working all the out of a negative he utterly condemned; but no one was his superior in manipulating a negative to improve its pictorial value, by masking, subduing, and combining; and further, by using a pencil of light by which he could literally work as with a crayon on a print which he deemed needed treatment. He felt that appliances of this kind were legitimate enough for a dark and careful character, but that to abandon such aids, in his strong disgust of the falsehood which the modern mode of tampering with negatives had introduced into what he regarded as the art of truth.

A SUGGESTION.

BY A LITTLE PHOTO.

There is a question well worth the attention of the professional photographer which has scarcely yet been sufficiently discussed. It is, do we take the public enough into our confidence, and cannot some of us, by the
issuing a few hints as to the capabilities of our art, and
also of its shortcomings (if one may admit), in order to
better understand between operator and subject? Many
have been done to elevate the public taste by photography,
and, on the other hand, much to degrade it. Is it not time a
bolder step were taken in the direction of elevating? Are
we not continually being tainted that our pictures are
nothing compared with the photographs of the Continent?
And is it not in most cases the sitter’s fault that such a state-
ment has a foundation in fact? Your average Englishman
and woman have an overweening sense of their dignity. They
cannot or will not descend to be a bit easy and natural
in a photographic studio; on the other hand, the Continental
photographer gets good sitters, for whether it is from the
habit of living, as it were, a more public life, or indulging so
much in the wicked pastime of dancing, it is certain that it is
easier to photograph foreigners than natives; the former are
easier posed, and are not afraid of making fools of themselves like your Englishman. It’s nice, after you have ex-
plained, and posed your sitter, to have the wind taken out
of your sails with “Oh! I know I look silly.” To hear that
has often made the bit of hair that nature and the focussing
cloth have left on my head rise in dismay, for where is your
explanation of it from that is the idea in the mind? Am
I not stooping too much? Where is any hand come to the bit?
I don’t look well side face.” These are a few of the troubl-
es of an English photographer even at the present day, not
counting the fact that shadow must be introduced but
springly, and you must be sure and bring out all the lace
and jewellry.

A cure is wanted for this state of affairs. I do not write
for the manufacturer, but for the artists and businesses for of course one
does not meet with such sitters; but of the want of taste in our
middle class there can be no doubt, and they will dictate to the
photographer. On the contrary, Continental people
understand good pictures, and have confidence in their
photographers. That is what we want to educate our patrons
—having confidence in their photographers.

There are several ways. One way is, as suggested above, to
issue tracts about our art, which has been done already by
the American photographers, but rather in some cases in an
offensive manner, at least to English ears. Something more
comprehensive and polite is wanted.

The best method would be to have local exhibitions of
photographs, to which admission should be free. That
would bring the art and its capabilities more before the
public, and so inculcate more the photographs’ guidance, there can be no question, for they would
naturally say: “The men that do these things understand
their business.” There are difficulties in the way, no doubt,
but where there are societies, such as at Liverpool and Man-
chester, it would be easily managed; and where there are not, let
the photographers sink their petty jealousies, and join
together, and get them up once or twice a year. A need
not be afraid, because B.’s pictures are better than his, that
he will lose trade. Don’t let them be personal advertising
 mediums, but only exhibitions to draw public attention to
the art, and elevate taste for good versus bad photographs
It would run out the quacks in time, and back-alum
photography would suffer; but it would raise the art and its
professors in public estimation, and raise the social status
of photographers immensely.

Even in small towns where two or three are gathered together
it could be done, and have some effect in the desired direction;
and in large towns there ought not to be any difficulty in
getting up such exhibitions, if the photographers’ so much
boasted love of their art is a fact, and not a mere clap-trap cry.

**THE ACTION OF SUNLIGHT ON CERTAIN MINERALS.**

*BY DR. SCHUMANN.*

Many of our readers will, perhaps, be surprised to learn
that the colours of certain minerals are very much in-
fluenced by the actinic rays. Singularly enough, the
action is observed only in the case of the hardest minerals,
and their colours are termed permanent stones. The poin
t of the actinic rays is maximum in the very hardest body known, the diamond.

According to the evidence of Dr. Flight, the sensitiveness to light of a coloured diamond is so great that it may be
compared with chloride of silver in this particular.

Our ancestors were acquainted with the fact that certain
coloured stones and gems bleached gradually in sunlight;
and hence, in the absence of light, the so-called chry-
sopras and the green emerald is acted upon in time by light, as I myself,
unfortunately, am able to testify, for an emerald ring I
have carried for seven years proves the fact conclusively.

But it is the diamond that behaves most remarkably in
the presence of sunlight. If coloured diamonds are heated,
the colour disappears more or less completely and for ever,
at any rate in most cases. At times, however, the colour
is only changed by heat, and through the influence of light the
same colour is restored. M. Martin, a noted diamond merchant, once exposed a
diamond to a high temperature in order to remove the brownish tints of the same, and he converted the gem into
a rose-tinted diamond. M. Caster tried the same experi-
ment with a brown diamond, and this, also, assumed a
rosy colour. The most singular thing, however, was,
that the colour was only visible in the dark, and in four
five minutes it disappeared—as soon, indeed, as it was
exposed to daylight. Then the gems assumed again a
light brownish colour. This change took place in a room
where, therefore, no bright light could penetrate.

Another diamond, of a dirty yellow colour, was heated
to a glow in a porcelain tube with hydrogen, and then
allowed to cool; the colour disappeared, but not its brill-
ience. As soon as this diamond was exposed to daylight for a period of six or seven minutes its original
yellow colour came back again. The experiment was
repeated, but this time the diamond was heated in chlorine
at a higher temperature; the colour again disappeared,
and could not be remarked in the dark; but as soon as it
was exposed, even for a few minutes, to daylight, its
original colour returned.

These phenomena have, no doubt, some relation to
phosphorescence, and the difference in coloured diamonds
may be compared with the analogous contrasts in char-
acter of the phosphorescent pro; erities which different
diamonds exhibit after being exposed to powerful light
rays.

**Correspondence.**

**DISEASES OF PHOTOGRAPHERS.**

Sir,—I have read the sensible and practical comments,
in your last week’s leader, on a letter of your correspondent
"L. L. F.,” with great satisfaction. I have read your other
remains, from which any of your readers who may be in doubt will, I trust, derive confidence and comfort. I have been a
sealous amateur photographer for upwards of twenty-four
years, and having been intimately associated with many
amateurs and professionals, have failed to observe any
peculiar disease which could be referred to the practice
of photography. Diseases of the eye are not infrequent among photographers, but they are not, I
apprehend, more common to them than to others where
brain work is a chief motive power—such, for instance, as
literary men, artists, musicians, &c.

The vapors of ether, alcohol, and acetic acid—the main
factors in the dark room—are well known depressants;
did to these, ill-restituted dark rooms, irregular marks,
anxiety to produce first-rate work, pressure of business, and uncertain exercise in the open air, and the wonder is, not that one occasionally falls out of the ranks, but that many are not more or less seriously injured.

Dabbling with bare hands in the toning bath (as I have often witnessed), carelessness in the use of chemicals (such as soda and bromine acid in the rough) used sometimes on cut or abraded fingers, is not rarely the unsuspected cause of mischief. Of the inconstant use of this salt I was, as you know, for two years once the victim, as was also lately that eminent artist, M. Silvy.

I would, then, earnestly say to all photographers, amateurs (professional, especially to the latter), let each make it a part of his religion to take good care before entering his studio—a good brisk walk—filling his lungs with pure fresh air, and as often as possible go into the open air at intervals of his work; take extra care that his dark room be thoroughly ventilated; secure some fixed hour for his meals, with which no engagements should be allowed to interfere; avoid alcoholic liquors (which aggravate the condition of nosophores), handling cyanide and pyro, and keep his hands well washed, not only the toning back (for, as I once mentioned in your columns, chlorido of gold is an energetic poison, and apt to cause ulceration of the skin).

I am not aware of any reason for ever suspecting that photography is a predisposing cause of diabetes, Bright's, or other allied affections; indeed, I know too well that they often arise as mere accidents where the conditions of life are unexceptionably good; and I am only re-iterating my own excellent remarks when I express my full conviction that, when ordinary prudence and intelligence are exercised, there is nothing in the practice of photography likely to be detrimental more than in the pursuit of any other occupation.—I am, sir, your obedient servant.

A Physician of Forty Years' Standing.

NEW LIGHTS IN PHOTOGRAPHY.

Dear Sir,—I have lately read a new mode of producing artificial light for photographic purposes, communicated by the ex-President to the Photographic Society, May I ask if there is any difference in the effect or advantage of the different lights, which was used, with much success in days gone by, and was very economical, although, since deposed by the magnesium light? And also, is there any danger of explosion? As a boy I used to make an explosive powder of nitre and sulphur, causing all sorts of mischief in the kitchen (where I experimented), and alarming the neighbourhood,—the only advantage being the cleaning of the chimney, and saving the cost of the sweep.

EQUIVALENT FOCUS OF A PORTRAIT LENS.

Sir,—The following is, I think, a new method that I have discovered for finding the equivalent focus of all lenses used in photography. It is tolerably accurate, and very simple. Go into a room where you have a view through the window of some distant object which stands out prominently, place a table against the wall opposite the window, and on the wall fasten a sheet of smooth white paper. Lay the lens on the table, and slide it to and from the wall until you have an image of the window projected on the sheet of paper. Single out the prominent object, and focus it accurately with another lens, by trial; then measure the distance between the sheet of paper and the end of the lens-tube nearest the sheet; note it down, then measure the distance between the paper and the other end of the lens-tube; note it down also. Reverse the lens-tube so that the back lens now fronts the window; repeat the focusing and measurements as before. There are now four measurements. Add the four measurements together, and divide the total by four: the product will be the equivalent focus required. The process will be facilitated by unshipping the flange, &c., so that the lens-tube may lay flat on the table.

I. W. DAWSON.

THE PRESIDENT OF THE PHOTOGRAPHIC SOCIETY.

We have received the following for publication:

The Hon. Secretary of the Photographic Society of Great Britain presents his compliments to the Editor of the Photographic News, and begs to forward to him for publication the enclosed copy of a letter received by him from Mr. James Glaishee:

1, Dartmouth Place, Blackheath, February 17, 1875.

My Dear Sir,—Since the receipt of your letter this morning I have had under thoughtful consideration the acceptance or not of the post to which I have been elected. I have all along believed I had the confidence of the Society; and although I had resolved not again to return to the presidency, still, with such a large vote in my favour, it would seem to be ungracious on my part not to accept the proffered honour. This determination I have arrived at on account of what is expressed by old and valued friends, who say that it will be for the good of the Society that I do so. For these reasons I have resolved to accept the presidency of the Photographic Society. At the same time I fear that I cannot promise regular attendance, and I should wish it to be understood that I resume the chair but for a limited period.—I am, dear sir, faithfully yours.

JAMES GLAISEE.

COST OF PHOTOGRAPHIC EXHIBITIONS.

Dear Sir,—I am obliged to Mr. Spiller for his practical and official confirmation of my statement relative to the monetary results of the Photographic Society's Exhibition of 1873. It is unnecessary for me to occupy your space with an analysis of the actual income and expenses (which I only professed to give in round numbers), since Mr. Spiller's letter so clearly confirms my remark to the effect that the 1873 Exhibition realized a small profit to the Society, whilst that of 1874 was an actual loss, to an amount between forty and fifty pounds. I did not enter into any remarks on the causes of the loss, but Mr. Fry's letter supplies instructive comment, and shows that the late agitation, besides causing serious disorganisation and discord, has inflicted a serious monetary loss upon the Society. Faithfully yours,

J. H. BADGE PATTENS.

23rd February.

MANAGEMENT OF BALLOT FOR OFFICERS.

Sir,—I see, by various communications, that some little difference exists in the opinion of members as to the way in which the late ballot of the Photographic Society was conducted. Will you allow me to state that in the many societies to which I have had the pleasure to belong, I cannot learn that over the votes given for one office were allowed to be accumulated to add to another. Probably the scrutineers had some precedent which authorised them so to act. I enclose you a balloting paper for the approaching election of officers for the Medical Society of London, as I shall not exercise my privilege. Such paper, being filled up, is enclosed in a small envelope; this is placed in another with name of the society, and addressed to the President, and it is opened at a council meeting, when, if the member is entitled to vote, the unopened paper is given to the scrutineers. Thus absolute impartiality is secured. Party feelings are occasionally strong at elections, and some years since I remember more balls being taken from a ballot box than there were members present to vote. Of course, it was an accident.—Yours, &c.

HENRY W. DAVISON.
Procoedings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

"For the first time in the history of the Society the Report of the Council does not comprehend a full period of twelve months, inasmuch as the present council and officers were not elected until the 18th of May last, when a special general meeting was held to elect the officers for the past year. The council, however, be incomplete were we not to commence by referring to the resignation of the president's chair by Mr. Glaisher after six years of active and excellent service to the Society. Our late President has carried with him in his retirement a grateful recognition on the part of all the members of his steady and unyielding work, which he conducted its affairs during that term of office, and a considerable measure of regret that these services were not continued, especially after having so successfully steered the course of the Society through a period of difficulty and embarrassment. The thanks of the Society are due to Mr. Glaisher for this estimable service, and will remain recorded in its annals upon that ground.

"Notwithstanding the difficulties inherent to a sudden change in the constitution of the Society and selection of new officers, some good work has been accomplished. Thirteen communications have been read at meetings of the Society during the past year, and the usual exhibition held in October, which was well supported and contributed to by the members, and received favorable notices from the press of the metropolis. Mr. Crowshay's competition was the means of bringing some additional works under the same roof, and certainly added to the interest of the collection. The exhibition remained open for more than three weeks, and opportunities were afforded for examining the pictures in the evenings, and occasionally adding to the private view reserved for members and their friends at the opening ceremony on the 18th October. The total number of exhibitors enumerated in the second edition of the catalogue was 87, exclusive of the Crawshay competitors, and the Society received a considerable accession of new members from this list. The financial aspect of the exhibition will appear in the Treasurer's Balance-sheet.

"At a Special General Meeting, held on the 30th June, the designation of the Society was changed to 'The Photographic Society of Great Britain,' in accordance with the general system of ballot in future governs the election of president, treasurer, and members of council.

"Twenty-five new members have been admitted into the Society during the year, four have retired, and the council mourns the loss of a distinguished colleague in the late Mr. O. G. Bejlander, who died on the 18th ultimo, and in respect of whom an obituary notice is appended.

"Marking the advance of photography at home and abroad, the council notes the establishment of a new society in the West Riding of Yorkshire, and observes, with unmixed satisfaction, the fourteenth anniversary of the Belgian Photographic Association, which, still continue in active operation. Carbon printing has made some technical progress, and the gelatino-bromide and emulsion processes have been certainly advanced a stage. Preliminary lighting, as a means of reducing exposure, has been further studied and applied, and Woodbury printing popularised; but with so many facilities existing for the publication and discussion of photographic novelties, it is to be regretted that no greater triumphs have been achieved during the past year, and that the brilliant, but somewhat ill-considered, report to report success in the extended scientific use of photography as a means of recording the phases of the transit of Venus, which occurred on the 9th of December. On that occasion one of its most distinguished members, Captain Abney, took an unexampled part. Lord Kelvin, seconded by Mr. England, was conveyed to him in the following terms:—'The council have received Mr. Bejlander's resignation of his seat at their board with very sincere regret, and desire to convey the assurance of their deep sympathy with him in his illness, coupled with the expression of their most cordial regard.'

"By birth the son of an officer in the Swedish army, and by training an artist-student from Rome, Bejlander took up the practice of photography, and settled in the town of Wolverhampton, and there produced 'The Swedish Girl,' which was highly commended for its artistic merit, which gained for him a considerable reputation. Designed for showing the art capacities of photography, and the possibility of 'combination printing,' the work was sent to the Manchester Exhibition of Art Treasures, and was afterwards frequently described by himself in the columns of the 'Journal.' On the 6th of April, 1888, a full report appearing in the 'Journal.' Several works of more or less ambitious character, all distinguished for their high artistic excellence, quickly followed, the majority of them being shown at the Society's annual exhibition, ending with the Albion of Studies on the table in 1873, and 'Scrap of Expression' and a portrait of Gustave Doré in 1874.

"A paragraph contained in Mr. Bejlander's communication of 1859 reads now like a prophecy in course of fulfilment, and no one is required for reproduction in the form of a daguerreotype, (says Bejlander) a time will come, and that not far distant, when real art and photography will go hand in hand, the latter as a means to the artistic end. It cannot be otherwise: photography will be the holding of a mirror up to Nature; and the more thoroughly a mind is imbued with the love for, and a discernment of, the true in art, the better will it embrace and refresh itself at the fountain of its inspiration, and draw from its ample, but to many hidden, treasures.

"Several years past Bejlander resided in London, where he died, and having been a member of the 38th Middlesex (Artists') Rifle Volunteer Corps, was buried with military honours at the Kensal Green Cemetery, in the presence of several members of this Society, and many friends who mourn his loss.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The second annual meeting of the session was held in Queen Street Hall, on the evening of Wednesday, the 17th instant, when there was, as usual, a very large attendance.

The exhibition consisted of a series of pictures illustrating a tour through the North and West Highlands, and were the joint productions of Mr. Wilson of Aberdeen, Mr. Valentine of Dundee, Mr. Doorley, and several of the members who made the tour.

The President (Dr. Thompson) in his address, said that he thought it right to take the opportunity, when so many of the friends of the Society were present, to call general attention to the work which the Society was doing, and to the ordinary general meeting of the members, where papers on photography and kindred subjects were read and discussed from which much [mutual] benefit was derived, there were during the summer a series of the most delightful outdoor meetings, when, cameras in hand, the members roamed over hill and dale in search of the picturesque and the beautiful; and although they might not always be able to secure all they could wish in that line, they never failed to get fresh air, necessary exercises, and most genial social companionship; and, as a natural consequence, good health and much happiness. Those two branches of the Society's operations were carried on at comparatively little cost, but it was different with the third, and certainly not the least
valuable, part of the work in which the Society was engaged—he alluded to the popular meetings, of which the present was an example. The “popular evenings” of the Edinburgh Photographic Society had, he said, become an institution in the city. These gave gratuitously to many hundreds of the inhabitants an opportunity of seeing some of the finest productions of the camera, in our own or other countries; and by means of the generally interesting lectures which accompanied those exhibitions, they were also afforded a large quantity of valuable information. As those productions have increased, it would be very evident, cost a good deal of money, and the Society looked to the public to assist in finding the necessary funds. The public hitherto had responded very well, as would be understood from the fact that they had probably two hundred of what he might call non-photographic members; but those who were members was between a hundred and two and a half; and as the subscription was only five shillings per annum, he hoped that the Secretary would have many applications from gentlemen, and ladies too, who were willing to submit themselves to the ordeal of the hat-box.

Mr. Davis then proceeded with his lecture, in which he stated that, along with several of the members of the Society, he resolved to spend a few days in the North and West Highlands, for the double purpose of shaking the city dust out of their brains, and getting material for a popular evening. They left Edinburgh by train, arriving at Pitlochry at nine o’clock in time to catch the Lona (that prince of Scotch steamers), which quickly and pleasantly carried them down the Clyde to Rothesay, and through the far-famed Kyles of Bute to Ardrishaig. Instead of following the usual or royal route to Oban, they then divided, the one party being in the largest steamers, capable of doing only some eight miles, and the other seventeen. After a day or two of rest and work, they went next through Glencoe to Fort William and Corpach, in the enjoyment of Highland air and “mountain dew,” and so well pleased as to have been in the latter part of the enjoyment, that, out of gratitude, they unanimously carried Ben Nevis as an honorary member of the Society, thus proving them to have been a set of “tight’uns” (Tighties). From Corpach their route led to the Caledonian Canal to the famous Falls of Foyers, and thence to Inverness. In the Highland capital they enjoyed themselves much, and secured some good pictures, and proceeded through Culloden Moor to Aberdeen. They were not fortunate enough to find Mr. G. W. Wilson at home, but made the best of their time by visiting some of the largest granite works in the world, and then started for Balmoral. Here, of course, they wanted to try their plates; but, having omitted to get the necessary order, they were somewhat afraid that a difficulty might occur with the old woman who kept the gate at which they wanted to get in; and to let you see the result of the experiment, however, proved an “open sesame,” and all went well for them. They afterwards discovered that there was no necessity for even the expenditure mentioned, as any ordinary piece of writing would have answered the purpose, the old lady being perfectly innocent of the laws of chemistry. They then went to Braemar, in expectation of being present at the annual “gathering,” which has made that place famous, but found that they were just too late by a week, and had to content themselves with a picture of it, which was shown on the screen. Here some pleasant days were spent, and some excellent pictures secured. The return home was through the heart of the Grampians by the passes of Cluny and Glenhee, the first halt being made at Blairgowrie. Here there was neither time nor opportunity for photographic work, but the loss was fully compensated for by a visit to see the national drama of “Cromwell’s Brig” performed in the Theatre Royal, a canvas erection, which, if not quite up to the usual mark, had at least the great qualification of being thoroughly ventilated, and where they saw the company feasting on a real shovell brick at a low charge—not for permission to the boxes—but for permission to the boxes—of three pence each. From Blairgowrie they found their way to Bonnie Dundee, where some pictures were also obtained, and thence through the kingdom of Fife back once more to Auld Reekie, very much delighted with the tour.

The pictures were unusually fine, and elicited the almost continuous applause of the large audience.

On the motion of Mr. Dobie, a hearty vote of thanks was given to Mr. Davis, and also to Messrs. Wilson and Valentine for their share of the pictures exhibited.

West Riding of Yorkshire Photographic Society.

The annual meeting of the Society was held at the Victoria Hotel, Bradford, on the evening of Monday, the 20th inst., Mr. J. W. Gough, President, in the chair. There was a numerously attendance of members.

The minutes of the last meeting having been read and confirmed, the following gentlemen were elected as members—Messrs. J. Bottomley, J. Beldon, W. M. Arundale, and A. Coe, Bradford; Mr. S. S. Priestley, Huddersfield; Messrs. Wm. Huggon and G. A. Huggon, Leeds; Messrs. Wadsworth, J. Whiteley, and H. Woodhead, Halifax; and Mr. Cattford, Halifax.

The rule announced for discussion— namely, as to the propriety of the Society’s holding exhibitions and offering prizes for competition—then came under notice.

Mr. Smyth (Halifax) suggested that the words “the Society shall offer prizes” be altered to “the Society may offer prizes”.

This proposition met with general approval, and on the President putting the rule in its amended form, it was unanimously carried.

Mr. J. Howarth then read a paper on “Warming Studios”, and laid on the table a large diagram of his heating apparatus which was inspected by the members with great interest.

Mr. Whiteley stated that he had much pleasure in testifying to the efficiency of the stove and its great heating power, as he had one in operation for some time.

In reply to a question from Mr. Howarth, Mr. Howarth said that his apparatus might be fitted up at a cost (roughly estimated) of about three guineas.

A communication, for members’ use only, from Mr. W. H. Brunton, Whitehaven, “On the Acceleration of Exposures,” was then read by the Secretary.

On the motion of Mr. Smith, a vote of thanks was unanimously accorded to the gentlemen who had contributed papers.

Mr. Greaves having kindly consented to demonstrate the development of carbon prints at the next meeting, the proceedings terminated.

Talk in the Studio.

Fuming Albumenised Paper.—A correspondent who has had considerable trouble in obtaining rich, brilliant prints from fine, but somewhat thin negatives, having adopted our advice to try fuming, has been singularly successful, his prints at once becoming rich and vigorous, as well as delicate. He says:—

“I write to thank you for your suggestion (which has in my case proved most valuable) that I should famine my sensitized paper in the same way as fuming albumenized paper, and I am satisfied that the result was excellent. Without having dried the paper or strengthened my silver solution (which I have always carefully kept neutral), or without having intensified my negatives, I can now get satisfactory prints by adopting the fuming with ammonia. I tried the experiment without much hope of success, but it was entirely successful. They then议ed to be the almost magical effect which the ammonia had produced. Instead of the disagreeable fogy red which has always hitherto appeared in the printing-frame, now I get an indescribably rich purple; the prints appearing bright blue in the early stages of printing, and gradually changing to purple; the shadows bronze much more than is the case with paper not treated. The toning and fixing also now proceed much more satisfactorily; but in the first operation it is somewhat more difficult to judge the right length of toning, because the prints are of such a colour before entering the toning bath that they appear more toned than is really the case.”

West Riding of Yorkshire Photographic Society.

The next meeting of the above Society will be held on the 1st inst., at 7.30 p.m., at the Victoria Hotel, Bradford.

Art Union of the Photographers’ Benevolent Association.—A circular has been issued by the Association in explanation of the postponement of drawing. It seems that some misunderstanding of the reply to an application made to the Art Union Trade for permission to use the name of Union after handbills and tickets had been issued, and the co-operation of agents solicited, nearly 3,000 tickets having been sold, and the proceeds paid into the London and County Bank, to the credit of the Photographers’ Benevolent Association, “at the last moment the Secretary received a letter threatening proceedings from a...”
THE PHOTOGRAPHIC NEWS. [FEBRUARY 26, 1875.

W. B. C. — As a rule, equal proportions of ether and alcohol are well suited for clearing collodion for ordinary purposes. For large plates it is well — especially in hot weather — to use a larger proportion of alcohol, the exact proportion being governed by the amount of contraction of the collodion. 

A. R. — A good half-plate negative will answer very well for enlarging purposes. The extent of enlargement depends on the distance of the lens from the subject, and the distance of the sensitive plate from the same. If, for instance, you wish to enlarge the object six times, with a lens eight inches focus, the camera must extend to allow fifty-six inches between the lens and ground glass, and the distance between the lens and plate will be a consequence between the two.

C. R. — We do not know any medical man in London who has given special attention to the diseases of photographers; indeed, we stated, all to whom we have ever mentioned the subject have taken the idea of our paper. It is not uncommon for you to have a letter in the present number. Dr. George Johnson, of 11, Savile Row, has made the study of Bright's disease a speciality, and diseases of the kidneys generally, we believe. We shall have occasion in receiving letters from you to mention.

F. W. R. Y. — We are glad that you find that fuming meets your difficulty. The print you send is certainly very fine indeed. With fuming it is manifest that your negative is just right. The probable reason that fuming is so comparatively little practised in this country arises out of the character of the negatives produced. As a rule, the negatives are intense and brilliant enough to give satisfactory results. A negative should be exposed fifty times, and then fumed. Fuming renders the paper more sensitive, and secures more rich and vigorous prints. It is therefore especially valuable with a certain class of negatives. With the same paper unfumed, and a negative which permitted a print without becoming too deep in the lights, you would also secure vigorous prints. But, as a general rule, we recommend fuming as giving many advantages. The paper in question is probably somewhat aided by the use of albumen in a state of fermentation.

T. J. A. — With the space at your disposal — that is, thirty feet from north to south, and fourteen feet from east to west — you may secure good lighting. The building will be, of course, a ridge-roof, and you will have glass on both sides. As a rule, it is probable you will find the light from the east side suit your purposes best; but you must work through by personal effort and patience. The business of a lithographic printer generally requires an apprenticeship, and photographic work involves the same amount of study and care, even if the subject is much superseded. When you have got a perfect plate, the task of "inking up," to get it into a satisfactory working condition, requires much skill and patience, alternate sponging with water, and inking with the roller many times, being revolving the plate in such a manner as to keep the ink well mixed, and to produce the best results. In lithography, the ink used is lithographic ink, not ordinary printers' ink. With great regularity, the inking of the plate is done by a printer, who is very skilled in the science, and the use of the lithographic roller made of leather, or one covered with india-rubber, is used.

J. W. DAWSON. — The best lens for a pocket apparatus would be a single-scope lens, which, of course, produces a picture three or four inches square very perfectly. 2. Such a lens may be obtained for the price you name. 3. Any good dry plates will answer for the purpose. If you are familiar with the working of bromo-gelatine plates, they will answer well.

J. C. B. (Sydney). — We have not had much personal experience of the printing of copies of engravings in line in carbon; but we can readily conceive that, under some circumstances, the difficulty you mention might be experienced, as there is less contrast between the lines, and it is possible that the printer might not be able to render the lines sufficiently distinct for the purpose you propose. The liquid you mention would be, for such subjects, to adopt the single transfer system. Another would be to give the glass plate a preliminary coating of india-rubber, and in transferring allow this film to leave the glass and remain as a permanent coating to the paper. It is rather likely that this latter would answer best for your dry climate; an extra proportion of sugar, or a trace of glycerine, would probably make it tougher and more suitable than the tissue prepared for the humid climate of England.

BRECKEN, LEMMER, AND CO. — The small yellowish white spots on prints may proceed from various causes, not always easy to trace, especially in the cases of black and white. The presence of impurities in the mounting board or mounting paper will cause such spots, as will also the fermentation of the paste, &c., used for mounting. Minute bubbles forming on the surface that is printed while in the mounting board will cause such spots, and these do not always become manifest until some time afterwards. Sometimes imperfection in the albumen water and the way in which it is used may be specially, if it has been kept in a damp place. Contact with brass powder used for "gold" printing will cause such spots.

WILHELM. — The best plan will be to communicate with M. ARNOUX, 24, Rue du Faubourg-Saint-Honoré, Paris, France. You can write to him in English.

GEORGE G. F. — As you have not mentioned the exact sizes of the pictures, it is difficult to say just what the size of studio.

A good general plan would be a studio with ridge-roof, 20 feet long, 10 wide, 13 feet as ridge, 7 feet as eaves. South side and roof glass, 8 feet each, with both eaves. South side and roof 8 or 9 feet, ridge and side lights coming to within about 20 inches of the floor.

G. W. P. — Each possesses merits, but we should prefer No. 5. This kind acts on a large scale. We refer the case of the thick papers and the thick urethane, which have been used in the manufacture of the thick papers, which are still in use to-day, and are marked for the deficiencies of a paper. The advantage of the thick papers, which are still in use, is that they are very durable, and that they are very much superior to the thin papers, which are still in use, and are marked for the deficiencies of the thick papers, which are still in use. The advantage of the thick papers, which are still in use, is that they are very durable, and that they are very much superior to the thin papers, which are still in use.
PHOTOGRAPHY IN AND OUT OF THE STUDIO.

A PHOTOGRAPHIC VOCABULARY—THE BELGIAN PHOTOGRAPHIC ASSOCIATION—A NOVEL PHOTOGRAPHIC ESTABLISHMENT.

A Photographic Vocabulary.—It would be a good thing if we could re-model our photographic vocabulary to some extent. Take the words positive and negative, for instance, the capital words in their way. Unfortunately, they do not at times mean exactly what we want to express, and then we are driven to employ such names as cliché, transparency, diapositive, and all sorts of expressions. It would be well, indeed, if we had the word cliché in our language, or followed the French example of having something in our vocabulary which means a transparency only, such as yields an impression by printing through, without giving result by reflection or negative. We have now to employ positive clichés so often, for one process or another, that their production is at present very widespread; and, in referring to them, one is often tempted to call them positive-negatives at the moment, to distinguish them from ordinary negatives. Again, we are given to talking about reversed negatives and reversed positives, with nothing of a rendering art in the least; although a photographer, of course, knows well enough what is meant by the terms. In describing our manipulations, too, we are sometimes puzzled how to render matters clearly; how to distinguish between the silver bath for dipping plates, and the silver bath for exciting paper; how to name the dark slide and shutter correctly. Again, in lenses, we call the whole womb in a lens, and when it is directed to unscrew the back or front of a lens, the pupil is just as likely to err in the matter as not; whereas, if we had a distinctive name for the separate lenses, in the same way, pretty well, as in microscopes, &c., calling the glass nearest the object the object-glass, and that one nearest the eye the eye-piece, no difficulty whatever could arise in the matter. It is the same thing with wet and dry collodion plates: one never knows whether, for instance, plate signifies the glass and sensitive film together, or the glass alone; and it is often necessary to read through the context of a paper to be able to form an opinion. One of these days, perhaps, we may have a dictionary of photographic terms which will set all these doubtful matters at rest for us.

The Belgian Photographic Association.—The new Belgian Photographic Association has begun life vigorously enough, and we sincerely trust it may continue its energetic measures for many a year to come. Its Bulletin, which is issued monthly, is quite a budget in its way, Professor G. de Vylder, Professor of Photography at the Ghent Industrial College, who is the president of the Association, being evidently its chief supporter. Some capital original papers have already appeared, as our readers are aware; for we have deemed them important enough to translate and reprint in full in these columns. Besides these communications, one special feature of the new journal is to give full abstracts from all the principal photographic journals of the day—French, German, Italian, and English—as they appear, giving a digest of each number as it comes out. As we have, too, already acquainted our readers, the Belgian Association, in a letter—whereas, it is true, the trimming, which it certainly does not show workmanship, was most probably not done by a worker, but by one who was not well learned; most probably by a boy, or a very careless assistant printer.

The Practical Printer in America.

XIX.

Cutting and Mounting.

There is no part of photographic printing that is more difficult, or shows more the taste, skill, and worth of a photographic printer, than this simple (7) process (as it is called by some) of "cutting the prints." Many have been the prints that have been ruined in the trimming, that were otherwise good. What would be the value of a print that was brilliant and most beautifully toned if it had been ruined in cutting?

I have often been surprised that prints, which are so beautiful in other respects, should be so abominably cut out as some have been that I have seen, when, at a glance at the prints, we could see that, with this exception, the printer thoroughly understood his business, for even upon the closest examination of it, before it was even burnedish, we could not see either weakness or coarseness of the paper in the slightest degree, too much bronzing in the shadows, lack of brilliancy, printed neither too dark nor too light, toned so finely that we cannot criticise it a particle, and, in fact, the whole print was a perfect gem, with this exception.

We will pause here a moment and consider. Undoubtedly all of those parts of this print which show workmanship were done by a workman of the most excellent one, too, at first-glance trimming, which it certainly does not show workmanship, was most probably not done by a workman, but by one who was not well learned; most probably by a boy, or a very careless assistant printer.

It has very often been said, and I myself have heard the expression several times, that "any one can trim prints who has been in a printing-room two days;" and I must here beg leave to differ, for, on the contrary, it takes years instead of days to trim them as they should be; and
it is owing to the belief of many photographers in the quotation I have above cited that the almost inexperienced help is told to trim the prints (so as to keep them busy, you know!), while the foreman printer and his experienced assistants are printing, &c., with only this advice (and often not that), "to be sure and have the nose or mouth come in the centre of the print." This part of the work should be entrusted only to an experienced person with a correct eye and good judgment as to the effect required in the finished picture.

In the cutting of the prints there are a variety of rules to be observed which tend towards the production of properly cut, and, although it is in some cases almost utterly impossible to give rules that will reach them, not knowing the style, &c., of the prints, as almost every operator possesses different ideas of what can be cut by the rules which will be given below.

The implements, &c., that are used in cutting the prints are:—One large plate glass, 10 by 12 inches in size, for cutting the print upon, and in case you cannot obtain a plate glass, a thick, level, ordinary glass of the same size will answer; one wheatsone; one Robinson’s photograph trimming knife, of a length of 8 inches; one scraper, or knife; one glass, size 7 by 8 inches, for cutting 8 by 10 prints; two 4 by 4 glasses, one 6 by 8 inches (for ordinary 4 by 4 mounts), and one 6 by 8 inches (for prints that are to be mounted on lithographic mounts); one oval 4 by 4 brass mat guide, size of opening 5 by 7 inches; two imperial sizes glasses, one 4 by 5 inches, which is the size generally used for 4 by 5 mounts, and one 5 by 7 inches, which is the imperial size glass wanted a little larger for special cases; one cabinet glass, size 2½ by 4½ inches; two cartes-de-viste glasses, size 2 by 3 inches, which is the ordinary size, and one 2½ by 3½ inches, which is made larger for the same reason as the imperial. When the latter class is used the prints should have been printed upon large card pieces, as the pieces that are obtained, as has been shown on a previous page, are a print not manufactured glass.

If printers wish to obtain a great number of small card pieces from a sheet of paper, they will then have to have their card-glasses shorter.

Have places for these things, and always keep them in their places, except, of course, when in use. Prints larger than 8 by 10 inches are very seldom cut, either before finishing or after, for they are not so likely to tear in the water during the future operations which they are destined to go through. In many galleries the 4 by 4 prints are not cut to any particular size, but trimmed as the larger prints are, and mats are also placed over them when they are about to be framed.

Considerable saving can be made as regards the expense of water and gas if every time a print is framed, if the prints are cut to the exact size and style being framed, especially in regard to the common carte. For instance, if you were to cut your 4 by 4 prints either oval or square before toning, the prints could then be mounted upon your 4 by 4 cardboard which was prepared for it, and, as will be shown, you can save considerable money in the course of a year or two by so doing, of course, in a greater or less degree, according to the amount of business the photographer has. To do this, however, it is necessary to have mounts prepared especially for the purpose, for if the prints were mounted upon the plain cardboard, and no mat placed over them when framed, the effect would not be at all pleasing.

(Waraw Studios.

BY JOHN HOWARTH.*

From what little experience I have had in the practice of photography I have found that the want of a proper system of warming and ventilating studios is seriously felt. My purpose in this paper is to point out what I believe to be the best means of accomplishing that most desirable object—a studio properly warmed and properly ventilated.

Every part of the room should be equal, or nearly equal, in temperature; all the air in the room should be constantly changed; and the foul air and deleterious gases, always generated in such structures, should be got rid of as they are formed, and give place to a constant supply of fresh, pure air.

There are three modes of warming studios usually adopted, to all of which, on various grounds, I strongly object. I purpose now to point out a plan which will be found to be better, cleaner, healthier, and cheaper than any or the best of the three.

The Open Fireplace System.—This is objectionable in a studio on account of its not acting uniformly all over the room; although by stopping up all the small defects for the inlet of cold air you can raise the room to a considerable temperature, yet the heat is oppressive and unhealthy on account of the foul air not being replaced by fresh oxygenised air. In addition to this, the fresh air which enters in any case to supply the fire being colder and heavier than the air already in the room lies at the bottom, making the heat very little felt when the heat is in the chimney, taking with it the greater part of the heat from the fire, whereby causing great waste of fuel. Cold draughts, smoke, and the photographer's enemy, dust, always attend the open-fire system.

The Close Stove System.—In a studio warmed by a close stove, there are neither draughts nor smoke, and comparatively little dust; therefore several of the disadvantages of an open fire are obviated. There is, however, one disadvantage under which it labours which is of great importance, viz., that only a small quantity of the air reaches the stove, and, being usually made of cast iron, the heated surface acts very injuriously upon that portion of the air which comes in contact with it, rendering it unfit for breathing, and leaving upon the photographic papers other unpleasant sensations owing to the large quantity of carbonic oxide and sulphurous gases given off by all heated cast-iron surfaces in contact with fire.

The third system—that of hot water circulating through pipes—is used to a certain extent, and, although less objectionable on many grounds than the other two, it has its disadvantages. The principal of these is, the great bulk of the apparatus, the expense of fixing, the chances of water freezing and bursting pipes, the constant liability of leaking from the pipes, joints, &c., and the great length of time required to keep the fire going before any effect of warmth is produced, and consequent loss of fuel. On this point I may say that I have the best authority for stating that half the heat of combustion is applied to use by any mode of warming, as in the system of circulation mentioned.

The system to which I will now call your attention is the one I adopt; it is, in my opinion, the best adapted to the wants of the photographer of any hitherto used. The introduction of the George’s calorigen,—with which all readers of the photographic journals will be familiar,—is a step in the right direction, but falls very far short of realising the full capabilities of the system.

I may here tell you that warming rooms to very high temperatures has been my closest study for the last twelve years. The result of that experience has been the production of a stove for small rooms, and of a furnace and apparatus for large rooms and public buildings, which, embodying all that can be done in securing the advantages to be
derived from an abundant supply of fresh, pure air, with the benefit of utilizing the heat of combustion to its fullest extent, in their application to warming and ventilating purposes.

I was led to the idea of their suitability for warming studios from having, some time ago, come into possession of a gallery of my own. Putting in one of my stoves I have had the benefit of experience in its use ever since, and I would not now like to be without it. I believe that an abundance of pure, dry air is what the photographer most requires for every part of his premises, and that it would be found to be better for his health, better for his comfort and pleasure, and better for his business. If he take up his cloth or leather to wipe his glass previous to coating a negative, what is more disagreeable than to find it already saturated with moisture? The glasses themselves, if cleaned some time beforehand, are bound to be coated with a film of moisture, which is a prolific source of streaks, and the films slip off in washing under the tap. All these annoyances disappear like magic under the influence of warm, dry air. The cloths are found crisp and dry, and, if the glass for the negative be held for a moment over the stove just previous to coating, there will be no such thing as the film dancing off the plate, or even of driving it off with reasonable usage.

In speaking of dry air, I do not mean that the air is absolutely dry, but that there is no visible moisture in the room, air having the property of taking moisture in proportion as it increases in temperature. Thus, at a low temperature, this capacity is very small, but it is rapidly increased as the temperature is elevated. Then any dampness or moisture ceases to be visible, and the warmed air (for instance, a sponge with water) takes up the moisture and holds it in solution. You can test this by taking a tumbler of cold liquid or a looking-glass into a room heated to no more than a hundred degrees warmer than you suppose to be dry air, and you will find the cold surface immediately covered with a film of moisture. However, if at any time the air be thought to be too dry it can easily be altered by placing water in a receptacle prepared for it in the stove, or by fixing a small fountain of spray inside a glass vessel in a convenient part of the room or studio. The effect would be both ornamental and very refreshing and agreeable when the room was warm.

An arrangement can be easily fitted at the top of the stove to receive wet negatives as they are made, where they will dry without trouble or care, and keep warm ready for varnishing at any convenient opportunity. The operator will find it the quickest, cleanest, and least troublesome means of varnishing he can possibly employ. Another advantage is that it is the most efficient ventilator, both for winter use with fire, and for summer use without fire. If the cold air to supply the stove be taken from a cellar or other cool place, it will aid very materially in modifying the high temperature which usually exists in all glass structures in hot weather. There is no difficulty in keeping baths, chemicals, and everything in order, as you can have a summer temperature, with a full supply of fresh air, all the year round.

I know it has been the custom for many years to cry down heated air as an objectionable mode of warming rooms, but I have found that the various theories put forth do not hold good in practice. The evils complained of do not apply to air which is constantly changed in the process of heating, but only when the same air is heated over and over again. I have often proved that air can be raised to very high temperatures without being vitiated. I have seen hundreds of instances of persons suffering from congestion of the lungs, and other disorders of the respiratory organs, relieved at once on entering a room warmed in this manner. I claim this as a point of superiority over every other form of stove—that, however hot it may be in the room, ventilation goes on in the same ratio. The hotter the stove the quicker the admission of pure air, and, however warm the room may be (and I have often tested it at very high temperatures), there is no feeling of oppressiveness through the want of purity of the air. This result is as attributable to the mode in which the heat is applied. I leave altogether the vexed question as to part of cast iron out of the question entirely, as it is only from a surface of best wrought iron that good results can be got; and I hold that no system of warming can be correct that does not secure a regular and uniform change of the entire contents of the room from the top to the bottom at regular intervals.

Taking the calorigen as the best stove in the market, I assume the points of difference to be greatly in my favour. First, I can warm a much larger area with the same quantity of fuel. Second, the air is in greater volume and purer. Third, where the conditions of the structure of the building will admit of it, I can warm two or three rooms as easily as one, and from the same stove. Fourth (which is of paramount importance), it will not cost above half the price.

In reference to the first and second of these points, I may say that the passage for air is much too contracted in the calorigen stove, and has to strike too many points of heated surface before it can discharge itself into the room. If you take a sketch of that stove, you will see that the passages are formed as shown in the figure, and in part of the calorigen, the end of which is terminated at the top of the stove. Now the air in its passage through this soiled pipe is compelled to strike so many points of heated surface that it must of necessity become superheated, and consequently, to some extent, vitiated. My stove is made as far as possible on the principle that air should only strike the heated surface once, and the air drawn off into the room; and, as I have before pointed out, the effect of the stove becoming very hot is not to vitiate the air, but to make it move quicker, and so warm the rooms sooner.

It is common in all close stoves for the ashes and clinkers to choke up the grate bars, and the fire has to be put out to enable it to be cleaned. In order to overcome this difficulty, I have put in a grate with an arrangement by which half the bars can either be drawn out or one end let down into the ashes drawer, the other end working on a pivot A. Thus every alternate bar being away, you can insert an instrument between the other bars and let down the dead fire into the ashes drawer. The loose bars being
THE NEW PATENT BILL.

As many of our readers are deeply interested in the subject of patents, we condense the following from an abstract, which appeared in the Engineer, of the new bill by the Lord Chancellor, recently read a second time in the House of Lords:

Clauses 1 to 4 are preliminary and definitive.

Clause 5 defines the constitution of the Patent Commission, which includes, as at present, the Lord Chancellor, the Master of the Rolls, and the law officers of England, Ireland, and Scotland, with five new Commissions, who are to be appointed by Royal Warrant. Two are to be nominated by the Lord Chancellor and three by the Board of Trade.

Clause 6 provides for the appointment of examiners, not less than two, and not more than four in number, to be chosen by the Lord Chancellor, who shall state in writing that they are "specially qualified for the office by legal or scientific knowledge."

Clause 7 refers to the appointment of referees, who "shall be persons specially qualified for the duty by knowledge of manufactures, art, or science." They are to be chosen jointly by the Board of Trade and the Commissioners every two years, and are to be "distributed in penalties according to their several qualifications."
Clauses 8 to 10 define the mode of making applications for patents. The applicant is to file a full specification of his invention, and any person who infringes the grant may be sued. "The use and publication of the invention by the applicant, during a period of six months from the date of the application, shall not prejudice the grant of a patent for it (which protection is the converse of use and publication in this Act referred to as provisional protection)." The application shall, "on the expiration of the prescribed time," be referred to an examiner and a referee. A transfer of a patent or a referral shall consider the application and relative documents, and shall report to the commissioners therein, and especially with reference to the following questions: (a) Whether the invention is a proper subject for a patent within the definition of Monopoly. (b) Whether the specification is sufficient. (c) Whether the invention is new, as far as they can judge thereof from an examination of former specifications and other details of patents and publications in the Patent Office. (d) Whether the invention is in the nature, wholly or mainly, of a combination of known machinery, substances, or processes. (e) Whether, regard being had to the last mentioned considerations, or to the consideration that the invention is not of great importance or utility, or for any other reason, it is expedient that the duration of the patent be granted for it (if any) be limited to seven years; or (f) Whether, by reason of the frivolous character of the invention, or for any other reason, it is not worthy of a patent.

Clause 12. The application, accompanied by the report of the examiner and referee, is always to go with the specification, is transmitted to the law officer, who will give his opinion. The application and opinions will then be made public.

Clause 13 to 16. Notice to proceed having been given by the applicant, a patent and a warrant will be prepared and submitted to the Lord Chancellor. If the law officers’ report is adverse, the applicant may, nevertheless, petition the Lord Chancellor for the grant and sealing of a patent, but, "any person" may petition against the sealing, and the patent will not be sealed, "unless a request for the sealing thereof is made within three months from the date of the warrant, and within the period of provisional protection. The sealing must take place within seven days before the expiration of the provisional protection, and not sooner, and every patent shall be dated the day of application.

Clause 17. Patents to extend to the United Kingdom, but may in certain cases also include the Colonies.

Clause 18. Powers are reserved to the Lord Chancellor to extend the period of provisional protection, and the period during which the patent may be sealed.

Clause 19 relates to foreign inventions and to applicants resident abroad, or to aliens wherever resident. The provisions are as follows: "1. A patent shall not be granted on the application, unless the applicant declares himself to be the first and true inventor, and no patent shall be granted in respect of a communication from abroad. 2. A patent shall not be granted after the expiration of a foreign patent for the invention, and, if, so granted, shall be void. 3. If at the time the application there is a foreign patent for the invention in force, a patent shall not be granted unless the foreign patentee is the applicant, and his application is made within six months after the expiration of the foreign patent, or the earliest foreign (if there are more than one). 4. A notice of every foreign patent for the invention existing at the date of the warrant for the patent shall appear by endorsement or otherwise on the patent. 5. The patent shall be subject of the foreign patent (if any), or of each of such ones of the foreign patents (if more than one) as first cease.

Clause 22 enables the patentee to amend his specification. No amendment will be allowed which would extend the patent beyond the original claims. Patents may amend after the patent is sealed.

Clause 23 provides that a patent may be revoked on petition to the Lord Chancellor, the proceeding by scire facias being abolished.

Clause 24. For the registration of licences and provisions for the registering of license deeds and assignments at the Patent Office, and do not materially differ from the regulations now in force.

Clause 25. Within two years of the date of a patent it may be revoked by a suit or any process in the Supreme Court of Judicature, or unless the patentee fails to grant licenses to proper persons requiring the same, on terms which the Lord Chancellor deems reasonable.

Clause 26 empowers the Lord Chancellor to allow extensions of patents which have only been granted in the first instance for seven years, but the whole term of the patent is in no case to exceed fourteen years from the date of the patent.

Clause 30. 30 to 33 deal with cases of fraud.

Clause 32. A patent shall have to all intents the like effect as against Her Majesty’s subjects, her heirs and successor, as it has against others. But the officers or commissioners administering any department of the service of the Crown may, by themselves, their agents, contractors, or others, use the invention for the service of the Crown, or for the accommodation of any department or commissioners and the patentee, or, in default of such agreement, settled by the Treasury.

Clauses 36 to 43 relate to procedure, and, with the remaining clauses, are mainly of a technical character.

The schedule gives the list of fees, which are generally the same as at present, the only material alteration being a reduction of 2½ in the cost of a patent for the first three years.

A DRY ALBUMEN PROCESS.

BY FRANK M. PICKERILL.*

First of all clean and albumenize the plates as follows: —

Coating for the Glass.

<table>
<thead>
<tr>
<th>Material</th>
<th>Quantity</th>
</tr>
</thead>
<tbody>
<tr>
<td>White of eggs</td>
<td>4 ounces</td>
</tr>
<tr>
<td>Honey</td>
<td>3 &quot;</td>
</tr>
<tr>
<td>Iodide of potassium</td>
<td>60 grains</td>
</tr>
<tr>
<td>Bromide of potassium</td>
<td>15 &quot;</td>
</tr>
<tr>
<td>Dry salt</td>
<td>5 &quot;</td>
</tr>
</tbody>
</table>

Place all of the above in a large bowl, and with a wooden fork beat them into a thick froth; then let them stand twenty or twenty-four hours to settle. When settled, filter through four or five thicknesses of cambric into a solution bottle. After the coated glass has been carefully heated over a spirit lamp, it must be allowed to get perfectly cool before plunging into the silver bath.

Silver Bath.

<table>
<thead>
<tr>
<th>Material</th>
<th>Quantity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Distilled water</td>
<td>1 quart</td>
</tr>
<tr>
<td>Nitrate of silver</td>
<td>4 ounces</td>
</tr>
</tbody>
</table>

When the silver is all dissolved, add six ounces of No. 8 acetic acid; shake well for a few moments, and then filter through paper. The albuminized glass is to be plunged into this bath quickly, then allowed to remain there for ten seconds, and then taken out and washed thoroughly, and placed upon its edge in a clean and dark place to dry.

Developing Solution.—Have ready in a pint bottle a saturated solution of gallic acid, and in an hour or six-ounce bottle a solution of the nitrate of silver, say five grains of silver to each ounce of water. When you wish to develop a picture, pour into a wide-mouthed two-ounce bottle as much of the gallic acid solution as you think will cover your glass; then place into the same bottle a very little of the silver solution; shake them together; then pour them over your glass, and the picture will soon begin to appear.

This solution is to be allowed to remain on the glass until the picture is fully out in all its detail; then the picture is to be well washed; when washed, it is ready for the hypsilophite of soda solution.

Hypsilophite of Soda or Fixing Solution.

<table>
<thead>
<tr>
<th>Material</th>
<th>Quantity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Water</td>
<td>16 ounces</td>
</tr>
<tr>
<td>Hypsilophite of soda</td>
<td>4 &quot;</td>
</tr>
</tbody>
</table>

Dissolve and filter. This solution is to be allowed to remain until the picture is all cleaned up; then wash it well, and put it on some clean place to dry. When the picture is dry it is ready to print from.

Note 1st.—Should small dark particles form on the glass while developing with the pyrogallic acid, you will at once pour off the developer and wash the plate and put on new.

Note 2nd.—When heating the glass over the spirit lamp drain all the albumen off you can; but should the film appear thicker at one end than at the other, flow it again, and flow off from the opposite corner, heating as before.

Note 3rd.—If you want the plate to work quicker, first coat with collofion, let dry, and then flow with the albumen as directed.

Time indoors of the original to three minutes, outdoors a half to three minutes. A great deal depends on developing, as it can be over-developed or under-developed, according to the amount of time given the exposure.

Note 4th.—In developing, place the glass on four wires standing on end supporting each corner of the glass, and when developing, place a piece of white paper under it, and you will soon see the picture appear.

* Anthony’s Bulletin.
GELATINE NEGATIVES.—INTENSIFYING BY PERMANGANATE OF POTASH.

We have been favoured with a letter from Mons. Chardon, of Paris, calling attention to a communication he made to the Photographic Society of France, at a recent meeting, on a method of reproducing negatives by the carbon process, and intensifying the image by means of permanganate of potash. The process consists in first producing a transparency on glass by the ordinary operations in carbon printing. From this transparency a negative is then produced, by a simple repetition of the same proceeding. Any degree of intensity may now be imparted to this image by the application of a solution of permanganate of potash, which is decomposed by the gelatine, intensity being secured by the precipitated manganese deposited. In making this communication to the Society, Mons. Chardon believed, of course, that it was really, as he knew that so far as he was aware, an original discovery. It was announced, however, that it was too late, and that a patent for this process had been applied for this year.

CAPTAIN ABNEY’S MODIFICATION OF THE STRONG ALKALINE DEVELOPER.

We gave, in a brief article, three weeks ago, some details of the mode of working dry plates employed by Captain Abney in his photographic records of the transit of Venus, whilst in Egypt. We learn since that a slight error crept into the formulation which it may be important to correct—the more so, that, in developing the plates in question, prepared by the albumen and beer process, he found a departure from Colonel Stuart Wortley’s formula necessary to perfect success. The principle of using a strong alkaline developer is due solely to Colonel Wortley, and it has proved very important and valuable in dry plate work. The formula, as employed by the Colonel for bromide plates, and found efficient by Mr. R. Manners Gordon for gum-gallic plates, stood as follows:—

No. 1.—Pure strong carbonate of ammonia 80 grains

Water ... ... ... 1 ounce

No. 2.—Bromide of potassium ... 120 grains

Water whole is self ... 1 ounce

The above ammoniacal acid ... 90 grains

by any other ... 1 ounce

If liquid ammonia were used, six minims of a 90-grain

NEW FORMULA in the place of the 12-grain

NEW FORMULA drops of strong liquid

water are deeply three drachms of water.

REMBRANDT PORTRAITS AND REFLECTED LIGHTS.
A SUPPLEMENTARY PAPER.
By G. CROUGHTON.

Some remarks in the excellent leader in last week's News suggest to me that our esteemed Editor has somewhat mistaken my meaning as expressed in the paper contributed by me to the South London Photographic Society, and upon the whole, I think I am justified in saying half light, with a very few touches of bright light, if that light be used with discretion and feeling; and no photographer with any pretension to artistic knowledge or taste would condemn this, or any other style of lighting, simply because it was unusual. I wish it therefore to be distinctly understood that I do not agree with the disparagement which has been bestowed upon the so-called Rembrandt style; my remarks were intended as a caution against the abuse of reflectors in lighting up the shaded side of the face. I had no intention of condemning the use of reflectors, any more than I had of condemning all retouching. I do not use them myself, because the studio I work in is somewhat narrow, and I can get all the effect which I require from a well-tinted half light somewhat in front of the sitter (or rather, I should say, over the camera); but in large galleries, where reflecting surfaces are a long way (comparatively) from the sitter, reflectors are absolutely necessary; but they want great care, combined with judgment and artistic feeling, in their use, for by their misuse, effects at once unusual and unpleasing are perpetrated.

It may be, as the leader says, that there are no conditions of lighting that can be really false or unnatural; yet I have had negatives pass through my hands upon which reflecting screens had done their worst, and the result has been quite false to nature, in the same way as over-lighting is false—destroying texture, and giving an effect to the face of being out of drawing. One would never, under ordinary circumstances, see a face under the conditions some of these portraits must have been taken. I have one now before me in which the reflected light upon the extreme edge of what ought to be the shaded side is as strong as the dominant light, but that reflected light is upon the face only, the drapery being in deep shadow, clearly showing what a small reflecting screen must have been held very close to the face on that side; the result is that the light under the forehead of what ought to be the shaded side of the face; the two edges of the face come forward, and the centre of the face being the darkest, and, moreover, between the lights, is made to retire. This, to say nothing of the two opposing lights in the eyes, gives an effect at once unnatural and painful. Photography may have (and, indeed, has) reproduced what was before it, but the operator had done his worst upon his model, and given her an unnatural appearance to commence with; therefore, I contend, the result is practically false.

To get the best effects in shadow pictures requires some study, and should be set about with a good knowledge of what is required. I can speak of my experience in the studio in which I am now working, which is some nine feet wide and eighteen feet long, with twelve feet of glass, and the ordinary ridge-roof; I can also speak of experiments in another roomier and taller studio, which was sixty long, forty feet wide, and some twenty feet to the ridge; in this gallery there was only one small part used of it, which in size would correspond very nearly with the one in which I am now working, all the other part being screened off. Here reflectors had to be used, but not the small hand reflectors I have been advised; they were large three-leaved screens, some eight feet high, each leaf being two feet wide, covered on one side by black and on the other by white calico. These were placed, as a rule, several feet from the sitter, the three leaves enabling the operator to adjust his reflectors to a nicety; as the end leaf would, if required, be brought somewhat in front of the sitter, the reflections were soft and subdued, as from the surface of a large mirror. In each of these galleries the background was placed in the same position, viz., brought forward so that its edge rested against the glass, and then sloping inwards away from the light, while the camera was moved to the opposite corner, so that the lens looked towards the light, the sitter being placed about midway up the gallery, all light being either stopped out entirely, or subdued at the camera end, up to the level of the sitter, thus leaving open the light behind and at the side, but not in advance. This is also my own practice; the side light up to the sitter is entirely blocked out with an opaque blind, the top light, to correspond, being subdued by a white one, which lets in enough light to relieve the dark shadow, and so secures sufficient contrast; my reflected lights are the natural reflections from the wall of the studio, which is papered with a light green-grey paper. I get more or less light upon the face by moving the opaque blind a little in advance or behind the sitter, as the face may require or taste dictate. My experience is in favour of bold lighting and full exposure; by this both brilliancy and softness are secured. Remember that you must see the details in shadow, or you will not produce a result that no shadow, however deep, should be without them. The difference in the exposure in my studio is that in a good light I get the ordinary lighted head in from eight to twelve seconds; the Rembrandts take from twenty to thirty seconds.

BROMIDE OF SILVER FOR PRINTING.
By W. T. DOVEY.

There is nothing new beneath the sun, depend upon it. Even our truly wonderful photography, despite its few years of existence, has its history linked with coincidences obtained from identical thoughts arising in the minds of independent discoverers and experimentalists. About six years ago, the late Mr. Trull, of Falmouth, undertook to prepare for him a photographic paper sufficiently sensitive for direct solar-camera printing; and knowing full well that no amount of chloride would yield what was wanted, I proceeded to experiment with bromides, which, used in admixture with albumen, gave what was needed in the way of sensibility, but the resultant prints were not so rich in colour, as are those produced with albuminized paper prepared in the usual way. It therefore occurred to me that a combina-

---

* Mr. Croughton is here under a misapprehension. Our leader was written before his paper was read, and could, of course, have no reference whatever to his remarks, which coincided. Cross ignorance in using either direct or reflected light may issue in results unusual and grotesque, which are so unlike the ordinary aspect of nature that they may be fairly called unnatural.——No.
GELATINE NEGATIVES.—INTENSIFYING BY PERMANGANATE OF POTASH.

We have been favoured with a letter from Mons. Chardon, of Paris, calling attention to a communication he made to the Photographic Society of France, at a recent meeting, on a method of reproducing negatives by the carbon process, and intensifying the image by means of permanganate of potash. The process consists in first producing a transparency on glass by the ordinary operations in carbon printing from this transparency a negative is produced, by a simple repetition of the same proceedings. Any degree of intensity may now be imparted to this image by the application of a solution of permanganate of potash, which is decomposed by the gelatine, intensity being secured by the oxide of manganese deposited. In making this communication to the Society, Mons. Chardon believed, of course, that it was really, as he knew that so far as he was concerned it was an original discovery. It was announced, however, that Mons. Lambert, whose name is associated with a method of enlarging and finishing, had been beforehand, and had in October last secured a patent for this mode of intensifying. Others have also made claims in reference to the process, and Mons. Chardon, having been informed that the first announcement of the use of permanganate for intensifying as early as 1868, is good enough to express a wish that we should enable him to give publicity to his claims.

We are fortunately in a position to state the case very precisely. In the year 1868, it is true, we announced, as the result of some experiments of our own, the value of permanganate of potash for intensifying negatives; but these were ordinary silver images. It is to Mr. J. W. Swan, at a later date, that photographers are indebted for the process of intensifying images in gelatine by the use of the salt of manganese. In the autumn of 1871, Mr. Swan favoured us with details of his discovery, and after verification we described the operations in the Photographic News of November 3rd of the year in question. It may be interesting to note, bringing out salient details from the article in question. Having described the operations of producing a transparency in carbon, we proceeded as follows:—The transparency thus produced is generally vigorous enough to reproduce negatives from; but if further intensity be required, it may be secured by the method which we shall presently describe. To produce the same transparency process is repeated in all its details, using the transparent or black. When the negative has been developed, it remains to be intensified; and it is in this part of the process that the chief novelty consists. After thoroughly washing, a solution of permanganate of potash is applied to the negative, by which a process of intensification is secured similar to that produced on a silver image by the same solution. The permanganate is decomposed by the gelatine, and a precipitate of manganese oxide of manganese, of a rich chestnut-brown tint—or, at times, a brown inclining to olive, which is highly non-actinic—is thrown down on the image, readily producing printing intensity. The strength of the permanganate solution is not very important; we have used Condy's red fluid, which, diluted with three or four times its bulk of water, answers well. This method, we conceive, may be employed to intensify the transparency if it be found desirable to increase its vigour before employing it to print the negative. A similar method might be employed to modify the tint of carbon prints if desired.

The patent of Mons. Lambert, is, therefore, we fear, rendered invalid by prior publication of the process. The process itself, which is both simple and efficient, has, singularly enough, not come into general use. As an aid to reproducing negatives by means of carbon tissue it possesses much value, which has not been generally recognized. It may be found also to possess another use. One of the common complaints against negatives produced by means of the gelatino-emulsion process is lack of sufficient vigour to give brilliant prints. Here is a simple method of intensifying them, which it is probable may remove every difficulty.

CAPTAIN ABNEY'S MODIFICATION OF THE STRONG ALKALINE DEVELOPER.

We gave, in a brief article, three weeks ago, some details of the mode of working dry plates employed by Captain Abney in his photographic records of the transit of Venus, whilst in Egypt. We learn since that a slight error crept into the formula which it may be important to correct—the more so, in developing the plates in question, prepared by the albumen and beer process, he found a departure from Colonel Stuart Wortley's formula necessary to perfect success. The principle of using a strong alkaline developer is due solely to Colonel Wortley, and it has proved very important and valuable in dry plate work. The formula, as employed by the Colonel for bromide plates, and found efficient by Mr. R. Manners Gordon for gum-albite plates, stood as follows:

No. 1.—Pure strong carbonate of ammonia 80 grains
Water .......................... 1 ounce

No. 2.—Bromide of potassium 120 grains
Water .......................... 1 ounce

No. 3.—Pyrogallic acid 96 grains
Alcohol .......................... 1 ounce

To each dram of No. 1, add one minim of No. 2, and from one to six minims of No. 3, according to the density required in the negative. If liquid ammonia were preferred, the formula stood thus: six minims of a 96-grain pyrogallic acid solution, three minims of the 120-grain solution of bromide, and two drops of strong liquid ammonia (sp. gr. 880) added to three drachms of water.

In this formula it will be seen that each ounce of developing solution contained a fraction of one to three grains of pyrogallic acid, a fraction over two grains of bromide of potassium, and nearly six minims of liquid ammonia. Captain Abney's formula differs from this in containing nearly four times as much pyrogallic acid, no retarding—or, as Captain Abney phrases it, destrucrive—bromide, and an exceedingly diminished proportion of ammonia. The corrected formula, employed in developing the transit plates, stands as follows:

Pyrogallic acid .......................... 12 grains
Water .......................... 1 ounce

To this were added two drops of a 20 per cent. solution of liquor ammonia—in round numbers, something like one-twelfth of the proportion used in Col. Wortley's formula. The strong developer prepared by Col. Wortley's formula
gave, as we have said, most valuable results with emulsion plates, and also, we understand, with dry plates by various other processes. With the beer and albumen plates prepared by Captain Abney's process, and used in the transit records, the formula, thus greatly modified, was, however, found to be better than any of the others. I am glad to have the opportunity of stating in minute details important. The mode of intensifying with pyrogallic acid, citric acid, and silver, remains as stated in our former article.

REMBRANDT PORTRAITS AND REFLECTED LIGHTS.
A SUPPLEMENTARY PAPER.
BY G. CROUGHTON.

Some remarks in the excellent leader in last week's News suggest to me that our esteemed Editor has somewhat mistaken my meaning as expressed in the paper contributed by me to the South London Photographic Society,* and upon which it again I think perhaps I have not expressed myself sufficiently clear upon the question of Rembrandt portraits; I therefore take this opportunity of clearing up any misconception that may exist as to my real meaning.

So far from condemning all Rembrandts or shadow pictures, I am convinced, from my own practice, that in most cases a more characteristic and certainly a far more real light may be secured by a quarter of an hour spent in the half-light, with a very few touches of bright light, if that light be used with discretion and feeling; and no photographer, with any pretension to artistic knowledge or taste would condemn this, or any other style of lighting, simply because it was unusual. I wish it therefore to be distinctly understood that I in no way agree with the disapprobation which has been expressed upon the so-called Rembrandts as a style; my remarks were intended as a caution against the abuse of reflectors in lighting up the shaded side of the face. I had no intention of condemning the use of reflectors, any more than I had of condemning all retouching. I do not use them myself, because the studio I work in is somewhat narrow, and I can get all the reflected light I require from the hall, aided by the long light somewhat in front of the sitter (or rather, I should say, over the camera); but in large galleries, where reflecting surfaces are a long way (comparatively) from the sitter, reflectors are absolutely necessary; but they want great care, combined with judgment and artistic feeling, in their use, for by their misuse, effects at once unusual and unpleasing are perpetrated. It may be, as the leader says, that there are no conditions of lighting that can be really false or unnatural; yet I have had negatives pass through my hands upon which reflecting screens had done their worst, and the result has been quite false to nature, in the same way as over-exposing is false—destroying texture, and giving an effect to the face of being out of drawing. One would never, under ordinary circumstances, see a face under the conditions of the present portraits must have been taken. I have one now before me in which the reflected light upon the extreme edge of what ought to be the shaded side is as strong as the dominant light, but that reflected light is upon the face only, the drapery being in deep shadow, clearly showing what a small reflecting screen must have been held very close to the face on that side; the result is the same within six years from the hat upon the forehead of what ought to be the shaded side of the face; the two edges of the face come forward, and the centre of the face being the darkest, and, moreover, between the lights, is made to retire. This, to say nothing of the two opposing lights in the eyes, gives an effect at once unnatural and painful. Photography may have (and, indeed, has) reproduced what was before it, but the operator had done his worst upon his model, and given her an unnatural appearance to commence with; therefore, I contend, the result is not practically fair, but too taut a statement in minute details important. The mode of intensifying with pyrogallic acid, citric acid, and silver, remains as stated in our former article.

To get the best effects in shadow pictures requires some study, and should be set about with a good knowledge of what is required. I can speak of my experience in the studio in which I am now working, which is some nine feet wide and eighteen feet long, with twelve feet of glass, and the ordinary ridge-roof; I can also speak of experiencing another nearer situation, sometimes two feet wide, and of the largest I have worked in, which was sixty long, forty feet wide, and some twenty feet to the ridge; in this gallery there was only one small part used of it, which in size would correspond very nearly with the one in which I am now working, all the other part being screened off. Here reflectors had to be used, but not the large hand reflectors I have seen advised; they were large three-leaved screens, some eight feet high, each leaf being two feet wide, covered on one side by black and on the other by white calico. These were placed, as a rule, several feet from the sitter, the three leaves enabling the operator to adjust his reflectors to a nicety; as the end leaf would, if required, be brought somewhat in front of the sitter, the reflections were soft and subdued, and from the other, which had the white calico, were hard and bright. In each of these galleries the background was placed in the same position, viz., brought forward so that its edge rested against the glass, and then sloping inwards away from the light, while the camera was moved to the opposite corner, so that the lens looked towards the light, the sitter being placed about midway up the gallery, all light being either stopped out entirely, or subdued at the camera end up to the level of the sitter, thus leaving open the light behind and at the side, but not in advance. This is also my own practice; the side light up to the sitter is entirely blocked out with an opaque blind, the top light, to correspond, being subdued by a white one, which lets in enough light to relieve the dark shadow, and so secures texture. My reflected lights are the natural reflections from the wall of the studio, which is papered with a light green-grey paper. I get more or less strong light upon the face by moving the opaque blind a little in advance or behind the sitter, as the face may require or taste dictate. My experience is in favour of bold lighting and full exposure; by this both brilliancy and softness are secured. Remember that you must see the details in the eye or you will not be able to see up them and that no shadow, however deep, should be without them. The difference in the exposure in my studio is that in a good light I get the ordinary lighted head in from eight to twelve seconds; the Rembrandts take from twenty to thirty seconds.

BROMIDE OF SILVER FOR PRINTING.

[March 5, 1875.]

**ON NEW PRINTING METHODS.**

**BY DR. H. VOLCK.**

During the many years that I have been actively engaged in photographic journalism, I have had an opportunity of remarking that certain photographic novelties pass away without leaving a trace behind them, while others, which are far less deserving, make a great noise in the photographic world. Thus the pictures produced by Denier, of St. Petersburg, produced a vast amount of correspondence and Thomson's first bath for negative, &c. Many published details of the process openly, while others offered to divulge "the secret" for a sum of money varying from three or four pounds upwards; others, again, expressed themselves perfectly willing to communicate the whole of the details to me if I would interest myself in getting them appointed Court Photographers, &c. After all these experiences, one would fancy that the whole world was about to produce photographs a la Denier, but, as we have seen, only a few, a very few, have taken up the method. At the same time, this particular method of printing is not a very difficult one, and may be adopted with advantage, probably, by such photographers who have not a very large business, and who are unskilled in the matter of retouching.

The simplest way of proceeding is to print the negative in a bath of half a litre of the cliche one or several plates of mica, or films of white, dry, transparent gelatine. How many such films are necessary can scarcely be predicted at the outset, but a thickness of half a line should suffice. A few experiments are necessary to settle the question. Through this medium the cliche does not print sharply, and thus the outlines are softened, and spots on the face, as well as any wrinkles that may exist, are rendered less prominent. For this reason any previous touching of the negative is rendered unnecessary.

The peculiar waxy character of the Denier prints do not seem to be altogether approved by art critics, but the public generally seems to be very pleased with it.

More difficult to carry out are two more novel processes, which are offered for sale by travelling agents, viz. Van der Weyde and Lambertype processes. As regards these two processes, I think photographers in a small way of business would do well to abstain from them. Both processes yield, in the hands of skilled retouchers, results which are very taking with the public. I say advisedly "with the public," for I personally share the opinion of a photographer who recently said to me: "I do not find the Van der Weyde pieces at my taste, but the public will be enchanted with them, and I shall produce them, therefore, not from art motives, but from those of business." In addition, I may remark that my friend has, as yet, received but few orders for such pictures. We should all of us like to find ourselves up in the heaven, but the cloudy leaden-coloured sky, such as M. Van der Weyde surrounds us with, seems to please but few.

Photographers should be exceedingly careful of purchasing processes of this kind. It is well, in the first place, to see what the journals have to say on the subject, and to learn something of the verdict accorded by those in the Capital; the reason why sellers of photographic novelties usually avoid societies is generally because they do not desire to have discussions upon their inventions.

The negative of Van der Weyde is represented in a shading secured by means of graphite and gum arabic, and the plate is, is scarcely suitable for photographs; more sympathetically appears the new Lambertype, although the latter presents no novelty, being a negative retouching process of an elaborate character, which, it should be understood, is only adapted to very large negatives. Lambert employs it for enlarged negatives, which are, of course, more expensive. The negatives of this process are covered with fine structureless paper, and this is worked upon in a suitable manner with black lead. The negative itself, in order to be adaptable to the process, must be very thin. For this reason the application of the process is limited, and the more so because of the necessary routine in the matter of retouching the negative. The more making of strokes upon the paper is not enough, but we must know exactly where to do it, and it is impossible to describe; one must be shown. Those, however, who have seen the method carried out, cannot do likewise, unless they possess some amount of artistic skill.

In a modest manner I have for some time past used the device of covering my negatives with paper, and with the greatest success. If, for instance, it is necessary to produce a thin part of the negative, the foreground, for instance, from printing through, I paste over the back in this past a bit of tissue or tracing paper, and with a pencil work up such parts as I desire should be thrown up. In portraits I have often employed the method when the background has come out too light. I then cover the figure on the back with paper, the outlines being carefully attended to, and in this way I have secured the figure of a much lighter nature than the background. The background is pasted on too much because of its opacity, then I employ negative varnish, which is applied with a brush, and is more transparent.

All this, however, is not new, for I have employed it for many years already, and I should be very sorry to see anybody call it Vogel-type on my account. Indeed, as it is, I think we have quite enough types of one sort or another, with proper names attached, and may certainly dispense with any more.

**ON THE EDUCATION OF PHOTOGRAPHERS.**

When photography was in its infancy, it required its followers from all ranks of men. At first, it was the painters and draughtsmen with more business than artistic knowledge who occupied themselves with the matter, and worked the new art as if it were a gold field. Later, everybody gave its contingent of men and women to the art, all of whom cultivated it with much profit and advantage to themselves, for the demands of the public were at first very moderate indeed. People were so enthusiastic over the invention, and the magical work of the sun's rays, that they were glad to give a high price for any specimen of the new art, no matter whether it was good or bad. Moreover, the artistic knowledge of the public is not at my time very deep, the number of real art connoisseurs being exceedingly small. The true art critic can only be formed by studying the highest works of art in existence. But who has opportunity for this in our small town, and

---

*Photographische Notizen.*

*Photographische Mitteilungen.*
how many are there of those dwelling in the larger cities who make any use of their opportunity?

Everyone, it is true, is born with a certain amount of taste, some possessing much, some little. By education this is remedied more perfectly. In Germany a taste is cultivated for music especially, but not for painting or drawing. This given in schools being the main thing being not only to make pictures (but to sell them), and then he is instructed in the technical part of his work, so as to become a good operator; furthermore he learns to know the public, to practise himself in the arrangement and lighting of his sitters, and, finally, acquires the requisite skill in negative retouching.

All these things can only be successfully acquired by those who have been grounded in some scientific knowledge. Photography, as a chemical operation, requires a knowledge of chemistry. It is ludicrous to hear skilled operators maintain that one need not necessarily possess chemical knowledge. The truth of the matter is that they themselves know something of the elements of that science. They may not have learnt it at school, but they know very well from practice that pyroxylin dissolves in a mixture of alcohol and ether; that nitrate of silver is soluble in water, and common salt, when put in the camera, is a mixture that by phosphite of soda dissolves salts of silver, and so on.

This is all chemical knowledge, and if any one will take the trouble to read through the list of photographic defects that are recorded in the printed handbooks on the subject, he will find that a great deal of chemical knowledge is requisite to avoid such accidents. How often have we heard of the mechanical operator committing the greatest blunders in employing manganese, india-rubber, acid, or ammonia, simply because he had no idea of the chemical action of these substances.

The same mistakes are made with the optical apparatus, arising from ignorance of these instruments. Many obtain lenses after lens, from which they expect the most impossible things, and they obtain in the end no more than a blurrier in employing their instruments.

For this reason it is obvious that a knowledge of the outlines of optics and chemistry is very necessary in the education of photographers in the case of such aspirants who desire to become something more than mechanical workers. Before all, it is necessary that they should cultivate taste in artistic matters. This may be done in two ways. Examine books in sketching, and therefore give some time to retouching, and educate the eye as to aid in the posing of models; and by studying the history of art, in which are included examples or copies of the finest masterpieces of all time. Further, a course of lessons in perspective and anatomy may be added, for the latter teaches of one of the main points in portrait photography, the human form.

To undertake studies of this kind is, of course, only in the power of those with means. So long as there is no photographic academy at which aspirants can study, we would recommend all those who can do so, to reside for one year in such a capital as Berlin, and to make use of the opportunities there afforded. Here are to be found establishments where art-industry is especially fostered, and where talented youths for study and practice are provided with every convenience. This bearing on photography, viz., drawing, anatomy, art history, chemistry, photographic chemistry, and optics.

Those who use their time well may secure the proper scientific knowledge in six months, but for most students a year is not too much for the purpose. It is generally the wish of all young hardworking photographers to serve as assistants for some time in one of the more renowned studios in the capital. Unfortunately, the establishments in which anything can be learnt are very few, and the principals are not always in a position to take assistants. It is not because they do not wish to do so, but it is a well-known fact that a third person is in the way in taking a portrait. The time, too, is too valuable in a busy studio, and the attention of the principal is too
much taken up for him to pay any regard to a pupil. Not unfrequently is the complaint heard from pupils that, instead of being allowed access to the studio, they are employed only in polishing plates and in stopping out defects in prints, experiences which could be gained just as well elsewhere. In this respect only a photographic academy could help, in which pupils could be instructed in posing and lighting with living models.

A PHOTOGRAPHER’S EXPERIENCES IN THE LIBYAN DESERT.

BY PHILIPP REMELI.*

New Year’s Eve we solemnized as well as we could under the circumstances. We had no goose, neither would the good people of Farafrah allow us to catch a couple of ducks that were swimming about on the principal pond of the place. But we managed to get a turkey, and this, and a glass of grog brought with us from Europe, served to while away pleasantly the last hours of the old year. At midnight the servants got out our fire-arms, and we saluted the new year with many a salvo, and illuminated our camp with the aid of magnesium wire.

On New Year’s Day I made an excursion to the western portion of the oasis, about six miles from Farafrah. Professor Zittel, who had visited the spot the day before for geological purposes, had called my attention to certain interesting places in the vicinity. As I did not start till eight, and the camel that carried my baggage was a remarkably slow animal, I did not reach my destination till nearly eleven. In the meantime it had grown very warm, and as I could get no shelter for my tent, the temperature inside it, notwithstanding that a north wind was blowing, was 28° Reaumur. The bath and chemicals simply refused to act, and the desiccation of the film over the plate was of a most unequal character. The collodion film was still wet at the lower portion of the plate, while above it was already dry, and after treatment in the silver bath the well-known blue streak was visible. The silver bath became turbid, and caused the plate to fog. By strengthening the liquid, however, and adding a few drops of glyceric acid solution, these defects were removed.

All this took time, and it was fortunate for me that there remained still plenty of light to operate with. With a little trouble, I was enabled to take my first pictures of the desert. The exposure was excessively short. With an aperture of 1/40 of a second, using a diaphragm of ½ five seconds were sufficient, and a stereoscopic image was taken in much shorter time. The plates developed very flat, and required much intensifying. I attributed this to the short exposure which the general illumination of the landscape necessitates. In such landscapes as these everything is in a full glare of light, and in a few places only is there a patch of dark shadow; at a longer exposure, in which the plate would be rendered more dense, could not be made use of, as it would be untrustworthy, the shadows not remaining sufficiently clear. Only with a short exposure can we hope to be successful.

As the expedition was to start next day at ten o’clock, and I had not taken any pictures of Farafrah, I was up by time these pictures were undertaken without trouble. With the couches and rendezvous in the garden, I found our tents had been struck, and everything was packed ready for our journey.

But the Arabs who accompanied us gave us so much difficulty that we could not make a start. One of them, especially, was always playing some stupid trick or other. After a number of iron boxes had been filled with sweet Farafrah water for our journey to Dachel, this latter was ordered to empty some other boxes which had been filled at Bir Kerani, a day and a half’s journey from Farafrah, with brackish and scarcely potable water. Instead of doing as he was told, the man went and poured all the sweet water away, and left the salt liquid in the boxes. The trick was, of course, discovered, but the filling of the boxes again from the distant well took a long time. Other of our Arabs refused to proceed any further, because they said they had not prayed sufficiently to ensure their safe arrival at Dachel. They would not have finished their devotions till the afternoon, and the end of it was that the start was postponed till the following morning.

The first day’s journey towards Dachel was of little interest. We journeyed for nearly three days over an almost level track, 500 to 1,000 yards broad, bordered on both sides with sandhills, and a low range of mountains high, a sort of natural highway of gigantic dimensions and monotonous form, which we, for want of a better term, called a road. Slowly ascending, the path lost itself in a high plateau full of picturesque lime rocks and steep mountain walls, forming a labyrinth through which our camels stepped slowly and laboriously. As the beasts dared not be overburdened in this heavy and not dangerous portion of our journey, we all of us walked on foot, and the interesting nature of the landscape did away with any feeling of fatigue. Through a grand rocky archway, named, after the German consul in Alexandria, Bab el Jasmund, we came to the long-wished-for declivity stretching towards the oasis Dachel. A second and more distant one, over natural daggers, and the recent natural destructions of the mountain Tops, at one of the wells, known traveller Cailliaud, Bab el Cailliaud, gave us a view over the valley in the wilderness of the finest beauty, in the vicinity of the oasis.

On the 7th January, at four in the afternoon, we came to Gaar Dachel, the capital of the oasis; we were welcomed by the head officials of the place, and the next day moved into a house made ready for our reception, which, although of a somewhat tumbledown description, was nevertheless adapted to a sojourn of some days than our more airy tents.

In Dachel began my actual work. For the further journey west, Gaar Dachel was made principal depot, and the command of it was given to me, so that I had plenty of time to depict the interesting points around Dachel and the adjoining portions of the Desert. For the latter purpose I arranged excursions of my own, sometimes stopping out two or three days together.

In the upper portion of our house I established a portrait studio, in order to comply with M. Rohlf’s wish to secure some types of the inhabitants of these oases. For my purpose, I made use of a smooth cloth background, and a very stable head-rest. With the aid of an Arab sheik named Mohamed Daud, who was in good odour with the inhabitants, I was successful in securing pictures of a large number of these brown Africans. No fees were, of course, to be had, but, on the contrary, every model had the sum of one franc paid him for the sitting. Without this stipulation had been made, I should, I fear, have done but little business.

The weather during the time of my sojourn at Dachel was no way so favourable as my experience of Siut and Farafrah had led me to expect. Very often there was a powerful wind that materially interfered with my operations, and sometimes we were troubled with a samoom, which rendered the practice of photography simply impossible. After a wind has once begun to blow, it is some time before the sand has been loosened sufficiently to be carried on with it. A light colouring of the sand in the portion of this, which sometimes occurs very suddenly, is the first signal of the coming samoom. The sand is blown in streaks over the desert first of all, and only rises a little from the surface, so that for some time one may continue the journey feeling the sand eddying past one’s knees. As the wind grows stronger, the sand rises more and more, until one’s lofty seat upon a camel no longer affords shelter. The sand striking upon the skin produces a strong prickling sensa-
tion, and the fine particles are driven through one's clothes and into every fold of the packages.

As the wind grows stronger the sand rises high into the air, so that the whole atmosphere is impregnated with it; the sun appears red like a sharply cut disk in the heavens, and the sand fog is so thick sometimes that you cannot see fifty paces from you. Sometimes this fog divides, and then there are to be seen sharply outlined sand clouds of a similar form to those in the sky.

(To be continued.)

A FEW FACTS ABOUT ALBUMEN.

The Western Photographic News gives the following summary of facts about albumen:

Albumen is an organic compound found both in animal and vegetable substances. Its properties are best studied in the white of an egg, which is a pure form of albumen. It also abounds in the blood and chyle, and more or less in all the serous fluids in the animal body; it also exists in the sap of vegetables and in their seeds and other edible parts. Albumen forms the starting point of animal tissues. The chief component elements of albumen are carbon, hydrogen, nitrogen, and oxygen, with small proportions of sulphur and phosphorus. It is believed to be a definite chemical compound, though the exact proportions and the rational formula have not been definitely ascertained. Carbon forms fifty-four per cent. of it, nitrogen sixteen, and sulphur two. The disagreeable smell arising from the decomposition of eggs is from the generation of sulphuric hydrogen.

Albumen is capable of existing in two states: in one of which it is soluble, in the other insoluble, in water. As soluble in water, it is found in the egg, the juice of flesh, the serum of blood, and the juice of vegetables. Soluble albumen may be converted into the insoluble form in the following ways:

1. By the application of heat. A moderately strong solution of albumen becomes opalescent and coagulates on being heated to about 150° Fah., but a temperature of 212° is required if the liquid is very dilute.

2. By addition of strong acids. Nitric acid coagulates albumen perfectly without the aid of heat. Acetic acid, however, acts differently, appearing to enter into combination with the albumen.

3. By the action of metallic salts. Many of the salts of the metals coagulate albumen completely. Bichloride of mercury, acetate of lead, sulphate of copper, and nitrate of silver form insoluble compounds, and the egg is therefore used as an antidote to these poisons. The white precipitate formed by mixing albumen with nitrate of silver is a chemical compound of the animal matter with protoxide of silver, and has been termed albuminate of silver. Albumen also combines with lime and baryta. When chlorid of barium is used with albumen, a white precipitate usually forms. By long keeping, albumen loses its alkaline reaction, and becomes sour and more limpid than at first. Mucous and acid gums form a web form in it, which appear to be caused by oxidation.

Ammonia added to albumen is said to preserve it for a longer time, and a lump of camphor floated in the liquid has a good effect. Alcohol, ether, creosote, and tannic acid likewise cause the coagulation of albumen.

Correspondence.

LATITUDE AND LONGITUDE BY PHOTOGRAPHY.

Sir,—In your French Correspondence I see a naval officer has been applying photography to delineate oceanic storms. That our art-science has many valuable applications, other than that of portraiture, need scarcely be said; but that the purely scientific aspect of photography has but little inte-

rest to the general body of its professors I am pretty well convinced; and hence, being in possession of a means whereby it will aid, if not supersedes, the present means employed to obtain latitude and longitude from the sun at sea, I shall have pleasure in sending particulars to the officer in question if M. Lacan can supply me with his address, preferring so to give the method an opportunity of being useful, rather than lie in my desk, as it now, has done for over a year. Originally I had written it for non-nautical readers. Upon receipt of the required information, I will re-write it to suit changed circumstances.—Yours, &c.,

W. E. BATHO.

ALBUMENIZING PLATES.

Dear Sir,—I doubt not that many of your readers who may be interested in practical photography, particularly when preparing plates for the "dry process," have often experienced difficulty in smoothly applying the preparatory coating of albumen, unless they resort to the careless practice of first dipping the plate into water, which greatly dilutes the mixture, so as to seriously lessen, when it does not entirely destroy, its efficacy; and the result is, that the film will subsequently slip during development, and ruin the negative.

For a long time I experience great annoyance myself from this source, until I discovered that all difficulty could be removed by simply breathing upon the plate before pouring on the albumen, when the solution will run as smoothly as if the surface were the best of silks. During the process of development, the fluid shows any hesitation at any point, it is only necessary to breathe upon that particular spot, and the difficulty will be obviated.—I remain your respectfully,

J. HENRY WHITEHOUSE.

Hotel "Beau Rivage," Ouchy, Lausanne, Switzerland.

NEW LIGHTS IN PHOTOGRAPHY.

Dear Sir,—In reply to "Enquire!" in last week's News, will you permit me to point out that Moulé's light was a pyrotechnic composition of the same nature as the "Bengal light" used for signalling in the Royal Navy. It consisted of nitre and red ochrement (sulphide of arsenic), and must be burnt either in the open air or within a glass lamp, in case with good draught to carry off the arsenical fumes. The "explosive powder" mentioned by your correspondent was not likely to have been sulphur and nitre alone, but probably contained in addition carbonate of potash, which serves much the same purpose as the carbon in gunpowder. The old "pulver fulminans" was a mixture of one part of sulphur, two of pearlash, and three parts of nitrate of potash, and behaves in a very different case with good draught to carry off the arsenical fumes.

The "explosive powder" mentioned by your correspondent was not likely to have been sulphur and nitre alone, but probably contained in addition carbonate of potash, which serves much the same purpose as the carbon in gunpowder. The old "pulver fulminans" was a mixture of one part of sulphur, two of pearlash, and three parts of nitrate of potash, and behaves in a very different manner in the case of the mixture of sulphur and nitre with which I am acquainted.—Yours truly,

J. HENRY WHITEHOUSE.

Talk in the Studio.

THE PHOTOGRAPHIC SOCIETY.—At the meeting of the Photographic Society, to be held on Tuesday evening next, Captain Abney will read a paper detailing some of his photographic experiences in Egypt in connection with the Transit of Venus Observations.

A DAILY ILLUSTRATED NEWSPAPER.—On the 10th March a paper will be read before the Society of Arts by Mr. Henry Blackburn, on "The Art of Illustration as Applied to Books and Newspapers," when the feasibility of daily illustrated newspapers will be discussed, and some particulars of the working of the Daily Graphic of New York communicated to the meeting.

ASSOCIATION BELOR DE PHOTOGRAPHY.—This society, which is only a few months old, has already considerably more than two hundred members. A monthly Bulletin is published by it, full of excellent matter and photographic illustrations. A peculiarity of this Society, worthy of note, is the establishment of a section in each large city. The members of each section
most at least once a month, and communicate their labours to the central committees. The society also elects into honorary connection with its body, foreign photographers whose names have been associated with the progress of the art. At a recent meeting, Mr. J. H. Dallmayer and Mr. Wharton Simpson were elected honorary members.

MAGICAL LANTERN SLIDES BY TRANSFER.—Mr. Gordon R. Bennett, in the following note, states: "Thoroughly saturate plain Saxo paper with a solution of gum benzine in alcohol, one part of benzine by weight to ten of methylated spirit. When dry, press flat and albumenize, and sensitize in a 60-grain bath, the print being finished in the usual manner. Then let the strip of the glass to which the picture is to be attached be floated with a solution of gelatine, and place on a levelling-stand till the surface is just tacky; the picture may then be pressed in contact and allowed to dry. Then apply strong alcohol to the back of the paper, which will dissolve the gum benzine and leave a thin albumen film attached to the glass. There are many other processes, but I consider this the most certain."

A GOOD CHEAP BATH.—Mr. J. D. Long, in the Western Photographic News, gives the following: "The following is my plan of making a glass bath, durable, cheap, and reliable. Select two pieces of flat glass the required size. Cut three strips of glass, an inch or more in width, for the ends and bottom of bath. Take the three strips of glass, and cement them together with pitch or rosin, and on a smooth piece of paper, moisten one side of the paper with water and find the edges of the glass strips until perfectly smooth and even and they are all of equal width. To put the glass together use a cement of glycine and ground litharge, made thick as putty, and put on with a knife. Use wood clamps to hold the cemented glass together until dry. Take a tight wood box about one inch larger than the glass jar, and suspend the same in it, leaving half an inch space on the bottom, sides, and ends. Melt good beeswax, and, being careful not to have the wax too hot, pour in around your glass jar until it is full, adding the melted wax as fast as it settles. When you have a wax bath, lined with glass, which will last you a lifetime."

We Correspondents.

TYRO.—Full details of Captain Abney's albumen and beer process appeared in our Year-Book for 1874. You will see there, on reference, that any colloidion giving a fine, creamy film in the wet processes may be used. Extended bromide may be added for special work, and subjects in black and white of one to five figures of much contrast, or for dense masses of foliage. As a rule, the plates do not require backing.

O.K. —The whole thing appears to be a "cook-and-bull story," not worthy of attention. We have heard various versions of the story, and, on enquiry, we find that all are false or exaggerated. It was first stated that a printed circular for canvassing photographs was put in circulation. That, we believe, was the statement that letters were sent out, written on paper with the official stamp or heading of the Society. That, we learn, is just as false as the former. Next it is stated that being so written created an impression that the letters were official, and that the late president wished Mr. Glaser to be elected. The fact that no letters on the official paper were so sent out disproves of that notion; but, apart from that, it must be sheer nonsense to affirm that Mr. Spiller wished the election of Mr. Glaser, seeing that he had not even nominated him, but did nominate another gentleman. It is rather an odd notion that one member is not to ask another member of the Society by brute force a special officer whose election he believes will be beneficial to the Society. 2. Mr. Glaser was elected by the votes of considerably more than half the members who voted. The undesirable mode of dealing with the voting papers doubtless limited the number of votes recorded. The system of adding the votes recorded for one office to those for the election in another office appears to be open to considerable objection, and an election to which you refer was the result, we are informed, of the combined votes for two offices, either of which alone would have been sufficient to secure the nomination.

W. A.—There is a photographic society in Bengal, and it issues a journal at intervals. Various photographic goods may be obtained in the bazaars, but there are no regular dealers in photographic work. There are, however, great many copies of the Photographic News to India. This is the best we can do.

H.—The committee in question have not rendered any report, and, so far as we learn, have no intention of doing so.

W. C..—We have frequently described the process of fuming briefly in this column. Take a box of any kind—a packing-case will do—and line it with paper, to stop up all cracks and crevices; then place a saucer at the bottom containing half an ounce of liquid ammonia. Then, in the bottom of the sensitive papered tube, face outward, and close the box for ten minutes or a quarter of an hour. The paper will then be ready for the printing-frame. You may frame it up as you would any other sheet, and on the sensitive paper in the printing-frame.

C. E. P.—By the "platinum printing-process" we presume you mean the use of platinum for toning. It is not more to be depended on for permanency than gold toning. We have published formulae repeatedly. You will find some details in our Year-Book for 1874. We recommend, as before mentioned, a weak solution of the chloride of platinum: say one grain in fifteen ounces of water. The free acid, always present, should be neutralized by the addition of carbonate of soda. This should be added until a slightly alkaline reaction is manifest, when a trace of nitric acid may be added, just sufficient to give a very slightly acid reaction. This solution will tone prints to a fine black.

F. P. BULL.—Your cards possess some good qualities. There is a little too much front top light.

T. J. A.—The ground plan in your note indicates our meaning with one or two exceptions: the camera must be placed from the northeaster corner, so as to be directly opposite the background. We think you will find fourteen feet wide enough for all purposes, and more convenient than a greater width. The Year-Book which contains Dr. Coxe's article on glass-rooms, with illustrations, is out of print.

P. O.—In printing transparencies for the stereoscope on carbon you need not have any trouble. Place a mask on the negative with aperture of the size and shape required, making care to place it so as to include just that part of the negative you require. Cut your piece of sensitive tissue just the proper stereoscopic size, and place it carefully on the negative so as to bring the apertures of the mask in the proper position for the picture. Then, in mounting the tissue upon the glass for development, you simply take care to place the two evenly, edge to edge, all around, and the image must be in its proper place.

2. A transparency for producing an enlargement should be deeply printed, delicate, and full of detail.

KATHRYN.—You had better apply to Mr. Meagher, whose announcement you will find in our advertisement page. He is personally a practical worker.

NORTHUMBERLAND.—You will find much of the chemical information you require in Captain Abney's "Instructions in Photography." 2. If your images are so close together that you cannot cut out two the proper sizes, each including the proper amount of subject, the lenses should be separated a little more. The lenses should be about three and three-quarters to one another, or even four pictures. For printing the prints, the right hand picture, when mounted, should contain just a trace most of the right hand side of the subject; the left hand picture of the left hand side of the subject. Of course, you would not be able to mount in mounting. The object of cutting the negative is to transpose the halves, so that the print may be produced and mounted without cutting in two for transposition. The print is pretty good, but it is not as the subject exists altogether. It is the problem of how long the sensitive carbon tissue sent out by the Autotype Company will keep. Much, doubtless, will depend on the weather. It will keep best in cold, dry weather, and worst in warm, moist weather.

ARCHER CLARKE.—We will take care that your suggestion is conveyed to the proper quarter, and something of the kind will probably be done.

C. A.—We cannot very well enter into a comparative description of the various lenses you mention here. The new one is, however, an unquestionable improvement upon the old one, as regards by the same maker, and takes more of the character of the third you name, by another maker.

S. W. L.—We have no means of knowing whether you could obtain a situation as assistant operator or printer. Your best plan will be, either to answer advertisements for assistants, which you will see in our advertising pages, or to advertise yourself. In either case you would have, in answering applications, to state details of your qualifications, which we believe, under the circumstances, the negative in the specimens you send is slightly under-exposed and much over-saturated, so that the print is hard. As a print it is perfectly black to the eye. 3. For your trouble.

D. F. B.—Considerable discussion appeared in our pages during last year on the subject of the beer to be used in the albumen and beer process. But as beer is not, in any case, an absolutely constant product, it is not possible to point to the product of one sorts, is 17.44 per cent for the purpose. We believe that Bass's pale ale generally answers well.

Several Correspondents in our next.
as a means of investigating the laws of oceanic storms, and as soon as the paper in question appears in the Comptes Rendus, or official proceedings of the French Academy, we shall have pleasure in placing a more detailed account of the research before our readers. An ingenious suggestion was made some years ago by an officer of the French Navy to make application of photography to show the course steered by a ship. A sheet of sensitized paper was placed in the binnacle underneath the compass, and this had a tiny hole through which the daylight penetrated; the sheet of paper was drawn along underneath the aperture, and became impressed, therefore, with a continuous line. This line, as the vessel moved, indicated the course that the latter had been steered. Under certain conditions this plan was found to answer very well, but much care, obviously, was necessary in the arrangement of the apparatus, and, moreover, it could only be employed in the daytime. For these reasons no practical employment was made of this ingenious suggestion, which was, however, tried for some time by several masters in the French mercantile navy.*

*Alumen and Pigment Photographic Transparencies.—We are glad to notice that transparencies other than the alumen prints of the well-known firm of Leon et Levy, of Paris, are beginning to make their appearance in commerce. It is certainly high time that such charming productions as glass photographs should have a far more extensive sale than has hitherto been the case, the celebrated French firm we have just mentioned having pretty well the whole business in their hands. These Paris pictures are world-renowned, and for many years they were unapproached by any other works of the kind, saving, perhaps, those of the late Mr. Brees, of Sydenham. It is time, we repeat, that other clever photographers, both in this country and abroad, should compete in the production of these charming works, for it is, in fact, the only form in which photographs are done full justice to. Lastly, we have fancied—it may be only fancy—that pictures of this kind that we have had many years are scarcely so perfect now as when they were first purchased. The transparencies are still as sharp as ever, but, somehow, they appear more hard and glaring than formerly. In some cases the pictures are unpleasantly harsh and unagreeable, while in other cases, the advantage of sharpness or microscopic clearness. Whether this is due to our having lately become accustomed to transparencies prepared with pigment, and therefore of a warmer and more pleasant character than the alumen tone of the earlier pictures, or whether these are fading, to some extent, and hence are a little unpleasant to look at, we scarcely like to venture an opinion at present. But, on examining, very lately, a large series of stereoscopic slides of this nature, we could scarcely believe but that they had parted with some of their original freshness and tone. In any case, however, if we can obtain pigment photographs of a pleasant tint, and as sharply executed as the alumen slides, the former will, we doubt not, be much preferred by the public, by reason of their more agreeable character. The alumen slides, as is well known, is a very high one, and this circumstance alone, we should think, would be a powerful argument on behalf of photographs of this nature being more abundantly produced than has been the case for many years past.

A PHOTOGRAPHER'S EXPERIENCES IN THE LIBYAN DESERT.

BY PHILIPP REMEL.†

It was my eyesight that suffered most in the sandstorm I had to encounter. A strong umbrella gave me the best
shelter under the circumstances. The dry wind created also a feeling of great thirst, especially when it happened to be hot. You have to drink four or five times as much water as usual to quench the burning thirst. In our case, with our food exhausted, a hot samoon will often dry up the liquid in a few days, and in this way cause a whole caravan to perish.

The so-called Chasmin, which is felt in April and May, is, in fact, nothing but the samoon, only there is this difference, which the air is for about a day, it comes from the south, and is invariably very hot. It felt its effects already in March, when I went out to take a few pictures with my camera. Although the wind was then very slight, and, owing to the dull atmosphere, the sun had little penetration, the interior of my tent had a temperature of 30° Resumur. The chemicals would not act; a thick fog covered my plates when I developed them; the silver bath, as glacial acetic acid was of no avail, had to be doctored. I made use of a plan which had previously been most successful, and added cyanide of potassium to my bath. It was then placed in the sunlight and filtered. The latter operation was, however, a tedious one. That day I had employed two donkeys to transport my plates; and as these animals are, in the desert, of very small stature, I had to lighten them as much as possible, and the funnel was one of the things I left behind me. Under these circumstances I scarcely knew how to help myself, but at last I managed, by employing a good quantity of paper, to make a solid filter which I held in my hands until the liquid had passed through. After that I was not troubled with fogging any more.

That the pictures were not very brilliant may be imagined, but they could, at any rate, be used. To obtain some contrast between lights and shadows, I exposed for a short time only, viz., three seconds, with the smallest diaphragm of my apianastic. The pictures developed very faintly, and required much intensifying; I had to keep my hot tent for about an hour with each of them.

A sudden samoon surprised me in the desert on the morning of the 18th January, as I was busy operating. My otherwise very stable camera-stand, to which the iron triangle of my camera was screwed, was thrown down by the powerful wind, and the camera broken against the heap of sand. A few negatives had been taken, and, which were upon a drainer on a flat stone to dry, were also exposed to the sandstorm, the sharp particles rattling against the glass. I tried to save them, but arrived too late, for the dry film was pierced with innumerable tiny holes. With my wrecked apparatus, and without any trace of my day's work, I lost for my part the desert, which never appeared to me so grey before. Out of curiosity I preserved one of the negatives which had been spoilt by the storm.

Arrived at Gair Dachel, my servant, who during the storm had firmly kept hold of the tent ropes, and prevented the misfortune being more extensive, took the camera in hand, and by the next day had put it again in a serviceable condition. He turned out quite a practical mechanic. The hazel wood of one of the plate-boxes was used for the repairs. Fortunately the lens had suffered no injury, and the ground-glass was only cracked, and was easily patched up again, therefore. To the circumstance that in cameras of Meagher's construction the ground glass is not tightly cemented, but is held in its place by two easy springs, I have to attribute the fortunate preservation of my focusing glass.

During the time I was occupied in taking pictures in Dachel and the neighbourhood, I never had any days free from wind, and for this reason the depiction of landscapes which plants and shrubs occurred was a difficult task.

The trees here (especially the ubiquitous date palm) shake much more than our more sturdy trees at home in Germany. For this reason it was that in no Egyptian pictures which I saw did I find the palm tree sharply rendered; the boxes play with the camera, and the camera with the objects. No Egyptian, landscape, such pictures are of little value. How difficult it is to portray the tree in a striking manner, many a painter knows.

The many acacias seen around Dachel, whose leaves and twigs are most small and delicate, as also the oil trees found in the vicinity of Farrafr, are excessively difficult to reproduce in the camera. For about a week it rained perfectly still, I was fortunate, however, by riding my time and watching for opportunities, to secure some sharp negatives. In taking views of this kind, the main thing to be attended to is to see whether the foliage is really at rest or not. Many a landscape photographer believes everything to be favourable, and exposes his plate only to secure an uninteresting image. On the contrary, from my experience as a landscape photographer, this happened to me several times in the depiction of tropical acacias.

A peculiarity of this otherwise very dry country is, that the air often contains large quantities of moisture, which condenses as clouds, and which, on one evening in February, fell like rain, and continued for a whole day. A steady rain was sufficient to keep everything wet out of doors, and make itself felt everywhere. Unfortunately, at this time, the roof of Professor Ascher's room fell in with a loud noise; and had not the heavy downfall, which had set in at midnight, ceased soon after, our whole house, and perhaps a large portion of Gair itself, would have been reduced to ruins. Everything is built of dried clay bricks, which fall to pieces when thoroughly wetted, the worst was to be feared. Such a powerful rain as that to which I refer is, however, of rare occurrence. Trustworthy people told us that they had not known such a thing these thirty years.

During my sojourn at the Dachel Oasis, from January until the 15th March, I secured one hundred and fifty negatives—not a very large number for so many days, but there was other work on my hands which absorbed many an hour and day of my time. Gair Dachel was the headquarters of the expedition. It was my duty to fit out the caravans proceeding through the desert, and to receive and put in order those which arrived. All the post and provision caravans came here. It was no very easy task, for employments had to be arranged for the men in contact with the lowest vagabonds one could imagine. Wherever the drabs could cheat, they took an opportunity of doing so, and every request made to them had to be accompanied with a present of money. The black fellows returning with the empty trains and camels from the desert were exceedingly rebellious, and I had many a struggle in order to maintain discipline; for as soon as they found themselves relieved from the personal supervision of the Great Man, as Rohibs was called, they became insubordinate. Nobody was more delighted than I, therefore, when at last my comrades returned from the desert in the middle of March, coming from Sinah by way of Farrafr. It was with much anxiety that their arrival was looked forward to, for as their journey had been so protracted a very long time, and beyond the term for which they had taken provisions, and forage and water for the camels, it began to be thought that the caravan must have perished.

(To be continued.)

ART-CRITICISM.

BY W. HILLSON.*

To be in strict accordance with its title this paper should treat of the art of criticising art; but my aim is merely, by

* A communication to the Edinburgh Photographic Society.
making some general remarks bearing on the subject, to arrive at some particulars regarding photography.

Photographic societies do right in fully discussing the science of photography; but, if too exclusively confined to that, an impression may be made that the means employed are more important than the end to be attained. At any rate, our art lags behind our science. The necessity that lies upon us graphically to express ourselves and the laws of art has already been well enforced here in the paper read by Mr. Mackay, and in remarks by Mr. Macbeth and others. I would add that it is also desirable that they should come to an understanding of what fine art is—it's capabilities and limits, and its relation to the artist, the public, and the times; for a thoughtful consideration of such questions in graphic art is to enable the artist to take his true position. As my remarks tendering in that direction must necessarily be concise, I have ranged them under separate headings in the hope of making them more distinct; and I cannot think that our time is wasted by having several evenings this session devoted to subjects bearing on photography as connected with fine art.

Science and Art.—On these two related yet opposed words the civilisation of the world turns; the one gathering in the abstract, the other in the material; the one concept, the other embodiment. Macaulay said, in his dashing way, that "every well-informed schoolboy has now more scientific knowledge than Sir Isaac Newton possessed." The reason of this spread of knowledge is evident. A few colossal intellects, looking into the secrets of nature, put them in form to be handed down as heirlooms—centres of ever-increasing cumulation. But art is the mirror. And mechanical art, a child of science, has kept pace with its parent. The master-spirit lays his hand (say) on steam or electricity, and a thousand lesser men carry them into endless ramifications. Thus in our century we have, for instance, the kingdom lighted with gas, steam navigation, the spinning jenny, the locomotive, the tabular bridge, and the stretched wire that carries our whispers to the ends of the earth. But, observe, this kind of art can be fixed in form, as measured by the yard or pound, and handed from generation to generation with the certainty of still increasing. Nothing of it is lost. But what of fine art? It is wholly different. Raphael, Shakespeare, and Beethoven cannot bequeath the secret of their working to be carried on by others. We cannot say here nothing of it is lost. The master-spirit dies and the art is lost. Fine art is no different from a different foundation; and the connection he arrives at—that is, the expression of his own individuality—is far bad in proportion as his faculties are well or ill balanced.

But the general community pursues quite a different line. They are apt to judge of a picture either solely by the subject it represents, or, if they have an extraordinary endowment of our common inheritance, vanity, they will pick you out before you can wink what they call a fault, and depreciate the artist by way of exalting themselves, or their admiration is wholly devoted to details. Their limited vision can see nothing in a picture but the clear, brilliant details:—"What a pretty boy!" says the old lady. "Oh! that darling of a dog!" cries the girl. And "How very clearly the twigs of that tree come out!" quoth pater familias. If any one doubt that such is the common run of art-criticism, he can easily put it to the test. Let him take a dozen or so chance companions, not artists, of course, one at a time, to see some pictures, concealing the names of the artists, and if he be not amused and amazed at the remarks he hears it is probably time for him to think of weighing himself in the balance.

As a sample of the world I shall give a bona-fide experience. Last autumn a great exhibition was held at the Smith Institute, in Stirling, which contains an excellent collection of several hundreds of ancient and modern paintings; among others a "Murillo," lent for exhibition by Sir William Maxwell Stirling—probably the finest "Murillo" in Britain, and certainly not surpassed in our public galleries. During my three visits of several hours each I saw only one individual person stop to look at this exquisite painting. Out of curiosity I took note of what were the chief objects of attraction; and I am sorry to say they were not the best pictures. "Distant twigs," "Darling dog," and such like details carried the enthusiasm. And these people were not mere benighted natives: they were mostly tourists, English ladies and gentlemen, kindly stopping to patronise provincial art, on their way to the Trooseachs to patronise provincial nature.

It reminded me of the long ago, when a tourist in his way, in a pair of red whiskers, walked and re-walked all day about the Brigg o' Turk, with a thrust-out hand, demanding a penny in a Gaelic shout; I, like a by-bosh Samaritan, offered him a shilling, which put him in such a fury that my discretion got the better of my value at the rate of eight miles an hour. So sad to see people peer paper to silver, while admiring a Brigg o' Turk or in a picture gallery! The conclusion I wish to state is that the taste of the general community is almost wholly confined to details, and that their opinion of works of fine art is of no great value, to say the most of it.

Details.—The passion for strikingly, startlingly graphic details is so universal that it may take rank among the "signs of the times." And it is not a bad sign, in so far as it indicates a spread of intelligence in the community, not capable of comprehending a subject in its totality, but still sufficient to take an interest in it. Yet this very proof that there has been some advance measures how small that advance has been. It is self-evident that when a subject, which has been restricted to the smaller circle of intellects trained in that department, is to be brought before the general community who have not been so trained, it must be supplemented in a different form and character. Ideas must be interpreted simply through their details. In other words, to suit the populace they must suit the popular comprehension and taste. A kind of deterioration inevitably takes place.

In literature we find how this has taken place, as the circle of readers widened throughout the community. Those which were formerly confined in tough volumes for the learned trained in that department are now broken into details for the popular magazines. The solid style of Hume's History has given place to the brilliant details of Macaulay. The thoughtful novels of Fielding have gradually degenerated into the endless details of Dickens. Dickens, with all his genius, wonderful invention, power of individualising, broad humour, and sentimental pathos, was chiefly indebted to his pen and the unique business of literary details. Fortunately for his unrivalled popularity, he had no faculty of generalising. His whole works were made up of details and details. His successors, with rare exceptions, in poverty of genius follow the path in which he triumphed, and get their novels read by stuffing them with details, especially of furniture and dress—said to be dearer and damper half of humanity—and with descriptions of Nature, which, fortunately, she cannot bear. No poetry is popular now unless it is choke-full of pretty details. The giants are out of date; Shakespeare himself has become heavy, and Milton decidedly dull. The argument might be strengthened by considering the theory of what is called the music of the future. Architecture pays more attention to
THE PHOTOGRAPHIC NEWS. [March 12, 1875.

details than to proportions. And what of art? Has it withstood the tide of this popular demand? No, it has not.

Fine Art.—The central principle of fine art is the same, whether embodied in poetry, painting, music, or other mode. It has one soul, so to speak, but different bodies; always the same thing embodied, whatever the instrumentality may be. It may be considered as having two departments, which, for the sake of distinction, I shall call the higher and the lower platform. When a picture gives details so as to represent its subject without carrying you in feeling beyond it, it is a work of art on the lower platform. When a picture gives the necessary details of its subject so as to carry you beyond it, rousing the vague impressions that are left in us by the experiences of life, so that we have a feeling of the universal, it is a figure for the art on the higher platform. I do not in one of his works, talking of grand music, say: "It dilates the heart into a capacity for the infinite." This is the same idea. He does not say that it suggests grand ideas, and excites the imagination: of course it does that, as almost anything may do—even the grunting of a pig, or the most wretched dabb. But, as fine art, it expands the heart, rouses the emotional impressions of our being, boundless feeling of the universal. Or, if it ascends from art, the lower platform, into fine art, the higher platform. Fine art includes art, and what it embodies will excite the imagination, as any work of mere art will; but as fine art it appeals directly, as its chiefest function, to the highest part of our being—the emotional—in which are fixed the impressions of our lifetime. To put it in a figure, the art on the higher platform, the noble idea of the one, and from which we draw out the precious wealth of life, and "thought" is merely a porter at the door, pointing the way and keeping things in order. Fine art does transport with the porter at the door, but only in order that it may pass on to draw out the inner wealth of the bank. Art never gets a step or two beyond the porter.

In the salmy days of fine art there were comparatively few painters—men whose innate genius impelled them to the work—and they had the advantage of working for a comparatively limited circle, and not the general community, who received their Madonnas, and the like, only as symbols of religion. In our latter times, as the demand for books increased, under the auspices of the march of intellect, so gradually arose a demand for pictures; and academies of art were instituted to meet the demand, and elevate the public in their art. Look at this fine art as a glass of another fine art. What would have been said of academies proposed to train men to become poets? The idea would have been received with more than a little laughter. Yet you might turn out a thousand men per annum to write the pretty sort of verses generally found in magazines, which are appreciated by the general public just because they suit their taste, being full of details and little else. In fact, your men would be poets in everything except "the vision and the faculty divine." You could not expect them all to be Homers.

Now, let us turn the idea back to the academies of art, and ask: "If you cannot train men to be poets on the higher platform, can you train men to be painters on the higher platform?" The answer must be the same in both cases. How may teach them the art of drawing, colouring, and composing, in so far as that can be taught, and they will turn out pretty pictures of all shapes and sizes; but you could not expect them all to be Raphaelles. Britain, like other countries, has its few pre-eminent painters, and many more of eminence, whose position would have been the same if academies of art had never existed. I do not allude to those who have been artists but for their training in an academy. Unable to reach above their height, these men necessarily remain on the lower platform, devoting themselves to the art of giving what Sir Joshua Reynolds calls "the punctilious delineation of details." When you consider that this style of painting is that most appreciated by the general community, and also the great number of men who produce such pictures, you see at once how the demand and supply fit into each other, and how the appetite for details is fed, and how such feeling increases the appetite. In fact, such has become the rage for brilliantly-graphic details, that even men who might achieve higher work are found accommodating themselves to the popular demand of the day. The public is the great patron now, and it is to be feared that the noble idea of the artist elevating the patron's taste may be resolved into the patron giving law to the artist. The pocket with the cash in it commands the situation.

These remarks are not intended to disparage the thousand artists of the day. They fill their place, do their work, and meet the public demand. They produce very pretty and pleasing pictures, that give delight to thousands; and the skill they, as a body, have acquired is quite wonderful. It is admitted now that there is a Scotch as well as an English school of painting of high standing, and the nation has reason to be proud of both. The annual exhibitions in Edinburgh, no less than in other places, show not only that there is a general excellence in manipulation, but that many artists have a feeling of fine art, which would probably bear more in proportion to the public taste. On the whole, these exhibitions have, no doubt, to a certain extent, a refining and elevating effect on the public; yet not of the loftiest kind. Pretty detail and high finish are too much the rule; and there is too little evidence of the simple greatness which results from a high aim and a lofty habit of contemplation.

(Co to be continued.)

CAMERA FOR LANDSCAPE WORK.

BY DAVID AIRD.*

While the resources of landscape photographers have received valuable additions in those varied dry processes which have been perfected during the past few years, to those especially who only practise our fascinating art in their hours of leisure and relaxation, the ease and certainty with which dry plates can now be prepared render them a boon which cannot fail to be felt and appreciated; but it is a curious fact that the more we advance in improvement, the more we feel how much may yet be done.

To workers of the wet process, the usual arrangement of camera and dark slide appears to be all that can be desired; but when we take an excursion into the country with two or three dozen of dry plates, the number of slides for their storage in the camera is almost preposterous. The size of each camera usually adopted by camera makers. In the centre of this upper compartment is the focusing screen A, held forward in its place by the two springs BB; the slide for raising the plates is an open frame, being simply two slides of brass, C, one passing down each side of the focusing screen and joined by a round cross-bar D, at both ends, a short distance from the side. The length of each strip of brass is furnished with a small projection, E, the use of which we shall presently see. In the under com-

A NEW PLAN OF PREPARING TRANSFERS FOR MECHANICAL PRINTING.

By H. L. Boalhettro. *

I cover a well cleaned glass plate with oxgall, which may be made to keep a long time on the addition of crocets. With the help of a bit of woolen rag I gently rub the surface of the glass in such a way as to distribute the oxgall evenly over the surface, without leaving any lines. I lay at a gentle heat, and while the plate is still warm I place it on a levelling stand. In the meantime I prepare a solution of gelatine made up of—

Gelatine ............................................ 5 grammes
Water ............................................. 1 part
Rock alum ........................................ 1 gramme.

This is thoroughly filtered through a bit of flannel after the gelatine and alum have been dissolved. While it is still warm, I pour it upon the plate treated with oxgall, and if the gelatine does not spread well I assist matters with a strip of cardboard. I then take a sheet of white paper, rather strong, and this I immerse in a dish of water, and when perfectly moistened it is drained by pressing against blotting-paper. The sheet is stretched over the gelatine, having a care that no air-bubbles arise, and that no gelatine gets on the back, and is left in this position till the next day. If the weather is not too damp the paper covered with gelatine separates from the plate of itself, but should this not be the case the margins are lifted by means of a penknife. The surface of the sheet is of a most brilliant nature, and may be kept in this state for an indefinite period.

When I desire to make use of it I plunge it into a three per cent. aqueous solution of bichromate, and suspend it to dry, after which it is exposed under a negative. As soon as the image appears in all its detail I plunge it in a solution of—

Nitrate of silver .................................. 1 part
Alcohol .......................................... 20 parts
Water ........................................... 50 parts

The surface then becomes of a brick-red, in consequence of the formation of chromate of silver. I wash with pure water, and then throw over the image some liquid ammonia diluted with three times its volume of water. Under this reaction the red that disappears (chromate of silver being gives place to ammonia), and there remains an image of a pale greenish tint, formed of oxide of chromium. After this transformation I wash again with water, and place the picture (face uppermost) upon a hard board, very clean, to which it is fixed with drawing-pins. A dry and very clean sponge is now passed over the surface, and in this way the excess of humidity is removed from the surface, after which the image is inked up by means of a lithographic roller.

The advantage of this process over those with which I have hitherto experimented is, that the ink attaches itself immediately to the impression, even when it has been over-exposed, and that one never gets reverse images, as is the case in other methods, when the undecomposed chromium has not been eliminated. The gelatine, by its association with alum in the first solution, and its immersion in the bichromate of potash bath, becomes perfectly insoluble, its consistence being argued by the effect of the silver solution.

To Restore Old Collodion.—Mr. R. A. Robison says, in the Western Photographic News:—To a pound of collodion add two pounds of water; shake thoroughly and let settle, when the cotton will all precipitate. The ether and alcohol being on top may now be decanted, and the cotton obtained from the water by straining through a piece of muslin. There will be a trace of water in the alcohol previously decanted, which may be removed by adding a little unslacked lime, and allowing it to stand a day or two. The cotton you have obtained mixed with an equal quantity of new, makes a fine soft working collodion. The ether and alcohol after above treatment may require the least quantity of acid. For this purpose, take one drop of muriatic acid, and add to one ounce of collodion, shake up and add a drop to your collodion. It may also be necessary to add new excipients. Filter the solution carefully to remove the lime. Should any of the lime remain in suspension, it will in a short time precipitate in the form of a white powder. Old and apparently useless collodion treated in this way I have found to work equal to or better than new.

A NOVELTY IN PORTRAITURE.—BOUDOIR PORTRAITS.

Regarding portraiture in its business aspects, the introduction of a novelty calculated to give an impetus to demand must always be interesting to professional photographers. This month, as an effort to introduce to our readers a new style of portrait which cannot fail, we think, if judiciously brought before the public, to secure general approbation, and create a new demand for photographers. The idea of the new style is due to Mr. Valentine Blanchard, who has felt the need of a popular style of portrait, for production and circulation in large numbers, like the card and cabinet portraits, but larger and more important than either. The size should be sufficiently important to do full justice to modern costume, without being so large as to interfere with the existing demand for large sizes, such as ten by eight and upwards, intended for framing. It should also possess symmetrical proportions, well fitted for doing justice to full-length standing figures—a style generally satisfactory, as permitting flowing draperies to be fairly rendered.

All these and various other desirable points are secured in the style which Mr. Blanchard recommends to his brother portraitists, as worthy of public favour, under the name of the “Boudoir portrait.” The size of the print is seven inches and a-half by four inches and three-quarters; the size of the mount is eight inches and a quarter by five inches. It will be seen that this gives precisely the same proportions as a card picture, and is, in point of fact, exactly the size of four card pictures. A narrow margin of mount, one-eighth of an inch wide, is left at the top and sides, and half an inch at the bottom, after the usual mode of mounting card portraits. The effect of a fine photograph in this style is singularly attractive and imposing, and must, we feel satisfied, take the public fancy at once. It will probably be difficult to secure uniformity in price; but there may be, at least, a uniform principle in charging. Mr. Blanchard charges, for half a dozen of the new style, two guineas, which is just twice his charge for the same number of cabinetas. As each picture is just the size of four card pictures, it will be wise to make four times the price. That is, in the same case especially as the larger size will make a greater demand on the artist’s resources to produce a perfectly satisfactory result.

The most effective subject for the new size will be found full-length figures of ladies in modern fashionable costume, to rendering full justice to which the boudoir portrait especially lends itself. The head in such a picture is about an inch long, or somewhat less than that. Three-quarter lengths, vignettes, are singularly charming in this style, and may probably in many cases involve less trouble in production. The proportions of the picture are, as it will readily be seen, admirably well suited to pictorial purposes for full-length and three-quarter figure figures, being as nearly as possible the same proportions employed by Gainsborough, Sir Joshua Reynolds, and other distinguished portraitists in painting a similar class of portraits. The shape of the picture relieves the artist of the necessity of filling up a vast space of background at each side of the figure, often a trouble in wider shapes, whilst it furnishes facility enough for the effective introduction of a few suitable accessories, or a little suggestive sketchy landscape effect. Another possible advantage of the proportions necessary in the figure, but an advantage which it will be wise to use charily, is the possibility of printing cabinets, or even cards, from the same negative where they are imperatively required.

An important question will arise in the minds of portraitists as to the mode of launching such a novelty. Fortunately, facilities for this are already provided. Mears, Marion and Co., of Soho Square, have already manufactured albums, cases, frames, mounts, and all aids to placing the boudoir portraits before the public in a complete form at once. Portraitists know well the importance of such aids to launching a new style. A complete set of specimens in mounts and frames, in cases and albums, have a much more important and attractive effect than when or three small examples and other disturbing agents induced to try the new style, and to purchase an album, will at once stimulate her friends to sit for similar portraits to fill her album. The new size will not involve any serious mechanical difficulties. A whole-plate lens will serve admirably for producing such portraits, and a ten by eight plate, used with a camera with repeating-back, will serve perfectly for two negatives side by side, and so absolutely printing in a complete form at once.

We commenced our remarks on this novelty by referring to it as possessing primarily a trade interest; and this is a form of interest which even the most lofty-souled artist should not affect to despise. Every art and every science in existence has its relation to such interests. One great aim of the tradesman whose ambition never soars above the shop is to stimulate the market, to create wants, to induce the public to do not simply what the artist wants, but things which, although the artist does not require them, they may be well enough pleased to have when once a desire for them has been awakened. In many important branches of trade a constant change in fashion is of set purpose secured, in order to keep up an equally constant demand for novelties. Mere wear and tear of an ordinary kind in the goods they supply would not maintain the trade, and hence the demand must be stimulated by the desire for change, which is initiated by changing fashions. To those who look at the matter in a strictly business light, a taking novelty will at once recommend itself; and to those who are unwilling to regard their profession as a trade governed by trade influences, it may be easily shown that arguments closely analogous are as applicable to the artist as to the tradesman. “A man’s favourite desire is to create wants: its first and most essentially educative operation is to stimulate a desire for something higher than the bare means of living. ‘Allow not nature more than nature needs: man’s life is cheap as beast’s.’” The mere means of living supplied, bare food for the body provided, the art instincts begin to assert themselves, the refinements of life are desired, and every advance in science and art creates as well as satisfies some higher taste or aspiration. Photography itself is a notable example. Portraits of beloved friends have become almost a necessary of life in every home, from the palace to the cottage; whilst a little more than a quarter of a century ago the portrait was a comparatively scarce luxury, which it never entered into many minds to desire to possess. Every good
novelty in photography is, then, worthy of the attention of all professional portraitists, whether their primary aim is to push a trade, or to work out one of the functions of art by creating and satisfying refined tastes and aspirations.

ANOTHER NEW STYLE.—IMPERIAL PORTRAITS.

In the preceding article we describe the novelty in portraiture which Mr. Blanchard has recently introduced under the name of the Boudoir Portrait. We have just received a series of very charming specimens from Mr. Abel Lewis, of Douglas, Isle of Man, produced in a style which he names the Imperial Portrait. It is practically a whole-plate portrait, mounted with a narrow margin, card fashion. To be precise, the prints are just eight inches and a-half by six inches and a-quarter, and the mounts, which are of buff cardboard, are ten by seven inches. The portraits are chiefly three-quarter lengths, and are probably printed from ten by eight or even larger negatives. In some cases the portrait is printed in a circle, with a grey margin. This plan is adopted with children, and is very effective and pleasing. As examples of art photography, we have rarely seen anything more charming than these pictures. Placing them side by side with the Boudoir Portrait, they are so distinct in size and effect that they need not clash, and may both fairly take the public taste, although, for a large run, it is probable that the Boudoir style will be best suited. Mr. Lewis has found the Imperials a success beyond his anticipation, and he has not found it interfere at all with the demand for larger sizes, but, on the contrary, to act as feeders if we may use the term, to the taste for larger work. Mr. Lewis states that he has long felt the need for something larger than the cabinet, in a similar style, and hence he adds independent testimony to that of Mr. Blanchard, to the effect that an opening for a suitable novelty or novelties exists. Mr. Lewis has already published some studies in the style which have at once taken with the public and sold largely. Many other leading photographers in the North are already adopting the Imperial size, we understand.

There is, perhaps, a slight disadvantage in the fact that the term “Imperial” has already been employed by some photographers in America to designate the cabinet portrait; but as it is manifestly unwise to use a new name for a familiar size, we may fairly leave the error to correct itself, and adhere to the use of the term Imperial to describe the noble size which Mr. Lewis has introduced.

TRANSLIT OF VENUS.

We are indebted to Mr. J. Smale, of Dartmouth, for a brief note on the operations of the observing parties in the south. Two of the gentlemen in charge of the photographic observations of the American party, being passengers on board the Edinburgh Castle, which put into Dartmouth after a rapid passage of twenty-four hours from the Cape, handed the note in question to Mr. Smale, who has been good enough to forward it to us for publication.

EDINBURGH CASTLE. March 5th, 1875.

The General Expeditions at Kerguelen, 49° S., 71° E.—The expeditions were successful. The American party observed ingress, and obtained sixty-five negatives with Venus on the disc of the sun.

The English Expedition.—An extract from Father Perry’s is as follows:—“We were fairly successful on December 9th, having obtained a first-rate observation of ingress at one station, and a very good one of egress at another. Egress was fairly observed at our first station. Photography has not been a success with us.”

The German Party.—The Germans were fairly successful, obtaining a first-rate observation and about sixty negatives.

The American party left the island on 12th January. The voyage to the Cape was very pleasant. The party then separated, part remaining on board the man-of-war Monongahela, and will go to Rio Janeiro, Brazil; and the rest coming to England, and then home. The parties left on the island were well.

G. W. DRYER, Photographers to IRVINE STANLEY, American Party.

MOTTOES FOR PHOTOGRAPHERS.

BY O. G. REJLANDER.

[The following mottoes, selected as applicable to photography and photographers by the late and lamented O. G. Rejlander, will interest all our readers. We are indebted for them to Mrs. Rejlander, who, having recently found them amongst her late husband’s papers, knew that they would interest us, and kindly placed them in our hands.—Ed.]

1. To an Operator.
   "She who hesitates is lost."

2. To a Printer.
   "Make hay whilst the sun shines."

3. To a Toner.
   "Let not thy left hand know what thy right hand is doing."

4. To a Retoucher.
   "A stitch in time saves nine."

5. To a Spotter.
   "Keep within bounds."

6. To a Mounter.
   "Act on the square."

7. To a Publisher.
   "Live and let live."

8. To a Purchaser.
   "A labourer is worthy of his hire."

9. To a Critic.
   "Ne sutor ultra crepidam."

FRENCH CORRESPONDENCE.

A SUBSTITUTE FOR RETOUCHING.—REPRODUCTION OF ENGRAVINGS AND HALF-TONE.—THE PHOTOGRAPHIC MANSIONS OF PARIS.—M. LIEBERT’S NEW FRANCO-AMERICAN STUDIO.

I have just received from M. Hassan, a photographer at Uran, a letter, in which that gentleman describes a method of dispensing with the retouching of negatives. The whole of the method consists in interposing between the negative and the prepared side of the sensitive paper during printing a light tissue, like crape or gauze, such as dressmakers make use of. The exposure is conducted in the ordinary way, only that from time to time, when viewing the progress of the plate, the tissue, which is elastic, is stretched, and the thread or network, changing its position, contributes to render the result very soft and delicate. In the case of large plates, such as one is obliged to print in big frames, closed by three or four covers, the tissue may be changed or removed altogether, after the printing has gone far enough for your purpose, leaving the impression, during the last period of its sojourn in the frame, in direct contact with the negative film. The author of this communication recommends especially the employment of a good varnish upon the clichés, and recommends that the operator should assure himself of the same being perfectly dry, so that there is no chance of the tissue adhering to the same. One need not fear that the dark shadows will lose their brilliancy—or, at any rate, that the prints will be produced of a grey, blunt character—for if the tissue
in a strong solution of iron (I used old developing solutions) till the film is saturated. They should be now well washed and again immersed, this time in a bath of a saturated solution of gallic acid. It is well known that a mixture of gallic acid and iron in solution forms ink. In this case the film is first impregnated with iron, and then converted into ink upon the application of gallic acid, and if, on examination, it is found that the negative or positive is not sufficiently dense, the same process can be repeated again and again, taking care each time to thoroughly dry before immersing in the iron bath.

They say "Out of evil comes good;" and if I had not read in the last week's issue of the News the article in which Mr. R. M. Monro stated that Mr. Monro had patented a method of intensifying carbon negatives, I certainly should not have thought of giving publicity to mine.

Trusting that this wee bit of information will find a welcome place in the columns of your valuable journal— I beg to remain yours obediently,

Charles Whiting.

Proceedings of Societies.

Photographic Society of Great Britain.

The usual monthly meeting of this Society was held on the evening of the 9th inst., in the Architectural Gallery, Conduit Street, Mr. J. Glaisher, F.R.S., in the chair.

The Chairman said that somewhat unexpectedly he found himself in the position of chairman amongst them. He would simply express a hope that all their proceedings would be characterized by unanimity and a general aim to secure the advancement of the science.

The Secretary read the minutes, which were confirmed, and Captain Vernay was elected a member of the Society.

Captain Abney then read a paper giving details of his photographic experiences in connection with the transit of Venus observations in Egypt, which will appear in our next. Some examples of negatives and transparencies were shown in illustration of remarks in the paper.

Some conversation followed, in the course of which Captain Abney stated that the temperature during which his photographic operations were conducted ranged from 40° to 90° Fah., giving a difference of 50°. He had found the dry and wet bulb of great value, as often indicating the probable exposure required.

The Chairman expressed the great interest and pleasure with which he had listened to the paper, and proposed a vote of thanks to Captain Abney, which was carried by acclamation.

Mr. P. York exhibited, by the aid of the magic lantern, a view of the station with photographic and astronomical erections used by Captain Abney at Thebes, and some negatives of the transit, taken by Mr. Bruton at Cape Town. After a vote of thanks, the meeting having been made special.

Mr. M. More than a resolution of which he had given notice, to the effect that payment of subscription for the past year be taken as a qualification for voting, in place of the offensive rule which had been recently put in operation, making payment of subscription for the current year imperative before voting at annual elections.

Captain Abney seconded the resolution.

Col. Stuart Wortley objected that the special meeting was not properly called according to the rules, which required it to be called by the council, or on the requisition of twenty members, and notice according to the rules had not been given to every member.

The Secretary explained that the special meeting was duly announced by the president at the last meeting, and due notice had been given in the Journal to every member.

In the by-elections the regular members followed on various points, in which Mr. Brain pointed out that the proceedings were perfectly in order, and in accordance with the rule. He did not agree with Mr. Hooper's motion, but contended that he was perfectly in order in bringing it forward, and the meeting was competent to deal with it, as it would be with another motion, of which he intended to give notice.

Mr. Stillman believed the meeting to be irregular and out of order. He was proceeding to point out that the Society was altogether disorganised and in a muddle, with rules drafted, accepted, broken, and misunderstood, but was interrupted by cries of order from the body of the meeting. After more desultory conversation, in which Mr. Hooper, Col. Wortley, Captain Abney, Mr. Bird, Mr. Stillman, Mr. Spiller, the Secretary, and the Chairman took part, Mr. Hooper's motion was put to the meeting and carried.

The Chairman said that the vote showed the feeling of the meeting; whether it possessed a legal value or not he could not say until he better understood the rules, which having been made in his absence, he was not prepared at present authoritatively to interpret.

The proceedings then terminated.

Edinburgh Photographic Society.

An ordinary meeting of the Society was held in the Bible Society's Rooms on the evening of Wednesday, the 3rd inst., the President, Dr. Thomson, in the chair. The minutes of the previous meeting, and the minute in connection with the death of the late Mr. Carl Rejlander, were read and approved; and the following gentlemen were admitted ordinary members: Messrs. David Small and Thomas Davidson.

Mr. Neilson read a paper entitled "Art Criticism" (see page 122), illustrated by several fine large and small photographs.

The President congratulated Mr. Neilson on the admirable and exhaustive paper which he had read. The paper was one of great value, and showed that he was thoroughly at home in the subject. He had given much study to it. It had been said that artists were born, not made; but even genius required education, and he thought the present generation enjoyed greater advantages than their predecessors, in so far that if one only brought his powers of observation into play, it was impossible to have a better work. The finding mass was the only one. He could remember the time when there was no gas in our streets, and when the shop windows were required for light, and not for show; now, however, matters were very much reversed, and we had in the windows of the print-sellers, the furniture dealers, and importers, a constant changing series of museum's pieces, or art galleries, that were daily exercising an abiding influence on all who cared for such study.

Mr. Norman Macbeth was very much pleased with the paper just read, and especially with the pictures by which some of Mr. Neilson's views were illustrated. He had worked and written in the right direction, and both pictures and paper went far in corroboration of what had been said, and strongly maintained, on a previous occasion.

Mr. Mackay had great pleasure in listening to the paper just read; especially as he pleased with Mr. Neilson's observations on fine art, which did not consist of minute detail, but in a proper working up of the ideal. This, he thought, was well shown in Mr. Neilson's pictures, which he did not hesitate to say were equal to anything of the kind that he had produced in Iceland.

Mr. Boyd agreed with the greater part of Mr. Neilson's paper, which he considered an able production. Much indeed depends on development, and he might say that where it was desired to produce texture, the least possible quantity of silver should be used, and as far as possible. More than a year ago, he read a paper before the Photographic Society of Scotland on this subject, and had at that time developed with gallic acid alone, without a particle of silver. He thought it might be held as axiomatic, "the less silver, the more texture."

Mr. Neilson said that there was less need for silver in intensifying than was generally supposed. He found that, after fixing, he could get a considerable increase in the intensity by the application of iron alone.

Mr. David Aird then exhibited, and read a short paper in explanation of a camera for large plates, which he had arranged, that, without dark slides, a dozen plates might safely and certainly be exposed in any required order. (See page 124).

Mr. Turnbull understood that there had been a camera patented—he thought by Cook—having the same object in view. He had not seen it, but Mr. Neilson believed that the one now on the table was in certain respects much more convenient and certain in action. One great advantage he considered to be the power to take the plates in any order, and that so easily and certainly that a mistake seemed impossible. Another important point was the fact that the camera contained in one piece everything required, so that nothing could be either lost or forgotten.

Dr. John Nicoll thought Mr. Aird deserved much credit for the perseverance and labour which must have been expended in having (unaided) produced such a complete result.
KEEPS QUALITIES OF THE PELICHEL
EMULSION.
BY WILLIAM ATKINS.*
In accordance with a promise made at our last meeting, I now wish to make a few remarks on the keeping qualities of pellicel emulsion prepared by Mr. W. B. Bolton's process.
It will be remembered that at the April meeting of our Association, the author exhibited two transparencies produced by means of this procès—of one upon a plate prepared the previous January, the other upon a plate made from the same batch of emulsion used on that occasion, and which had in the meanwhile remained in my possession untouched, being at the time eighteen weeks' old.
A few evenings since I again tried this old emulsion, and the result are now before you. The conditions observed were as nearly as possible similar on each occasion, the same negative having been used and the same exposure to gaslight (ten seconds) given. No gold was used for toning. The results, upon comparison, are as good as the previous one. The emulsion has not deteriorated in the slightest degree. A slight opalescence is observable upon drying the plate; but this may arise from the ordinary decomposition of the pyroxylene, which takes place with even plain collodion; or it may be caused by some chemical action traceable to the organic matter used in the emulsion, which, in this case, consisted of tannin, soap, and sulphate of quinine. The latter substance has since been found to exercise a very powerful effect as a restrainer, and it is very probable that its action does not stop there.
The plates prepared from this particular emulsion exhibit now, as previously, a tendency to slowness in development, but in that respect are in no way different to what they were thirteen months since, thus proving that no chemical change has taken place in the emulsion itself.
This, I think, fairly shows that the emulsion is possessed of satisfactory keeping qualities. Holding in view the additional twelve months' experience gained, and recent improvements in the details of the process, I think it holds out a fair prospect that a sensitive emulsion may be made which will retain all its good qualities as long as ordinary bromized collodion, or, indeed, indefinitely.
These remarks refer simply to the sample of emulsion I have possessed since January in last year, before the process was published by Mr. Bolton. Since that time improvements have been made in the details of the process, but the unchanged nature of this preparation is, I think, established. The pellicel previous to solution will undoubtedly keep indefinitely.

GLUE AND GELATINE.
As gelatine in various photographic processes, and glue for mounting purposes, become more extensively used every year, it is only natural the the readers to know something of the variable composition of these bodies as found in commerce. Mr. S. Dana Hayes gives, in the American Chemist, the analysis of various samples which he has examined as follows:

grades, and from different makers, showed the proportion of water contained in them to vary from fourteen to eighteen per cent., averaging seven per cent.; and the proportion of ash or mineral matter varied from three to seven per cent., averaging rather less than four per cent. Two of these samples contained about one per cent. of white zinc, and two of them contained sulphate of lime.
And of two samples of grade, one contained sixteen and a-half per cent. of water, and 2.56 and 3.11 per cent. of ash respectively. There was no oxide of zinc or sulphate of lime in these gelatines.

The presence of so much water was quite unexpected, and, as the quantity is nearly the same in fresh and in seasoned specimens, it is not a make-weight, although steam is very freely used in the rooms where glue is packed by the manufacturers. The carbonate of lime comes from the quicklime used for cleaning and preserving the animal matter, or "glue-stock," while the sulphate of lime is formed by the addition of small quantities of sulphuric acid during the manufacture, to neutralize the lime that is carried forward by the solutions of glue. The oxide of zinc is said to be added to "prevent souring," or the acidity caused by decomposition, and it also improves the colour of the glue; but it is not very generally used, and it is generally believed that it impairs the keeping qualities of the glue. I have heard of the use of sulphate of zinc, alum, magnesia, &c., by glue-makers, but I did not find any other substance than those named above in these specimens, which represented the article commonly sold and used.

The impure glues, or those containing the most mineral matter, became almost insoluble after they had been broken into small pieces, and heated in a hot air-bath (copper even), at 100°C., for two or three hours, until they were heated, they then soften and become dough-like, but do not dissolve when boiled in water for some time. The purer gelatines were not so much injured, and on boiling containing only 0.8 per cent. of mineral matter were not affected by this thorough drying. The solid sheet glue, while drying in this way, tansified, and became very porous; the frozen glue did not alter in structure.

Correspondence.

REMOVING EXCESS OF IODIDE FROM THE BATH.
Sir,—I have noticed that it has been recommended to add barium nitrate to the bath, either at the time of making it, or to rid it of excess of iodide. Allow me to state that those who are troubled with excess of iodide will find that to the bath solution barium sulphate be added, and shaken up on filtering, all excess will have been carried down. In certain chemical manipulations with clay I have been in the habit of using this to clear a water solution.—
Yours faithfully,
W. D. W. Abney, Captain R.E.

STRONG DEVELOPMENT.
Sir,—I notice with interest your article in last week's issue on strong development; but I ask leave to point out that the principle of strong development is the same, whether the strength of the pyrogallic acid or of the ammonia be reduced, so long as one of them is strong. You will remember that I have pointed out that the proportion of ammonia and pyrogallic may be varied indefinitely, according to the class of negative required, and, no doubt, Captain Abney's work being special, he required to modify my formula for his special case.
I beg to conclude by thanking you for the way in which you speak of my introduction of this new principle in dry plate work.—Faithfully yours,
H. Stuart Wortley.

INTENSIFYING GELATINE NEGATIVES.
DEAR SIR,—In the winter of 1873-74, having some carbonized papers to make, I found it desirable, in some instances, to intensify them, and after experimenting a little, I could intensify gelatine transparencies or negatives to any extent, and with comparative ease. I now purpose giving publicity to the means I employed, and I hasten to do so lest some more ambitious worker than myself should think of the same, and look it up from the photographic world, or in other words, 'improve it.'
These transparencies in my case were made in the ordinary manner, the tissue of the Autotype Company being sensiti-ised, printed, and developed on glass, using the Autotype varnish as a substrate. When quite dry, immerse them

PHOTOGRAPHY IN AND OUT OF THE STUDIO.
COPYING BY PAPER TRANSPARENCIES—Himes' DRY PLATES—THE VALUE OF SWAN'S DISCOVERY OF INTENSIFYING CARBON PRINTS.

COPYING BY PAPER TRANSPARENCIES.—Some time ago we mentioned the application of photography to the handy and architect, who found the process very handy for the purpose of making rapid copies of their plans and drawings, simply putting a sheet of sensitized paper under the tracings, enclosing the between a pair of glass plates to keep them flat, and bracketing the two together by a few American clips. Professor Alexander Hershel, of Newcastle, also gave our readers a description of the method he adopted for copying his tables and observations, employing iron salts in the process, which rendered his MS. and figures in blue characters. Photography the professor found so useful for copying in this way, never making a mistake in a fraction, a figure, or decimal point, or blurring over the abstruse terms to be met with in science, that he never employed any other medium, for he could always upon an exact exactitude without the trouble of having carefully to go over the copy and compare it with the original. Accountants, in like manner, we should think, would also find photography useful occasionally in this direction, as they could always rest assured that no error, however slight, has crept into any copy they have got the sun to make for them. One objection, more than any other, has perhaps摄影 in in the matter of copying of facts and figures in this way, and that is the circumstance that your work is not, as a rule, produced upon paper so transparent as to allow the light to penetrate freely. When one is not satisfied with white lines on a dark ground, and desires to print from a negative instead of a positive, the difficulty becomes all the greater, for it is next to impossible to get an impression from a photographic print produced under ordinary circumstances. Waxing the original may be had recourse to, but pressing the heated wax into the paper, besides being a tedious operation, may have the effect of injuring a document you desire to preserve intact. The discovery of Herr Füsscher, which has now been published some little time, may be made use of in this connection, with admirable results. This adhesive, as some of the experimenters may know, has invented a simple method of rendering paper transparent, and also of restoring its opacity again afterwards. One volume of castor oil is dissolved in two or three volumes of spirits of wine, and into this is dipped either plain paper or paper which already bears a drawing or writing of some kind. The mixture rapidly soaks into the paper, and makes it transparent; and, but a short time after the removal of the paper from the bath, the spirit evaporates, and a dry transparent film remains. In the case of plain paper, any design may now be traced or sketched upon it with Indian ink and such like pigments. Designs upon paper of this kind would copy admirably as clichés, for there is transparency enough for the rapid production by photography of a second, and consequently, a third, and so on, until the operation is stopped by its being necessary, if need be, afterwards as a negative. From the latter, good and vigorous impressions can be obtained in the right sense; and although, possibly, they might not be so suitable for all purposes as copies written or sketched by hand, they would, nevertheless, be perfectly trustworthy as regards their accuracy. Professional men who would thus employ photography for copying their tables, formula, or designs, would do well to use either washed albumenized paper and fumed pads of cloth or paper, or the durable sensitive paper sold in commerce, which will keep good a long time; for obviously they would find it very irksome were they called upon to prepare a bit of paper every time they wished to make a copy. Their original MS. or sketch can be changed back again to its former opaque condition by rinsing it in a bath of methylated spirit, which speedily washes out every trace of the castor oil.

Himes' DRY PLATES.—In a recent number of the American Journal of Science, Professor Himes, of Dickinson College, gives full details for preparing his photographic plates in daylight by desensitizing and re-sensitizing the silver compounds contained in a salt of bichromate of potash, which is used for this purpose, the surface of the light being annulled by pouring a few per cent. aqueous solution of iodide of potassium over them. If the plates, after dipping in the nitrate of silver bath, are rinsed, and then exposed for several hours to sunlight, or diffused daylight, and in this way rendered insensitivae, they may be dry and will keep for an indefinite period. Just before use their sensitiveness is restored to them by immersing them in a solution of tannin (fifteen grains tannin in one ounce of water), the latter operation being of course conducted in the dark. Unfortunately, this operation alone renders all the other advantages claimed rather questionable, since, after all, the sensitizing of the plates, and drying them in the dark, in an even temperature and sheltered from the dust, is just as most difficult and tedious manipulation connected with the preparation of dry plates. The subsequent sensitizing of Professor Himes' films with the tannin solution would probably occupy but a few minutes, but the drying of them would still necessitate some hours. Moreover, the mere fact of the plates being dried twice over is a grave question not to be overlooked, for the desiccaty process would, no doubt, tend to a repetition of the collodion, which would often prove the destruction of the plate, from the adhesion of dust particles in contact with the film. For these reasons, we do not think the process so simple of carrying out as others that have recently been brought forward.

The Value of Swan's DISCOVERY OF INTENSIFYING DRY PLATES.—Swan's discovery that permanganate of potash can be used for intensifying the carbon image will no doubt be largely made use of when carbon printing comes to be more vulgarized. Any one who has developed a pigment print upon glass, with a white sheet of paper underneath to watch when the action has proceeded far enough to give a good positive print, must have been surprised the first time he removed the paper and looked at the print by transmitted light. What would be a good vigorous picture upon a white basis is the mere ghost of an image looked at by transmitted light. The darkening, and nothing more, or more forcible colouring, is necessary before a good transparency can be made of it. By employing a blacker tissue, it is true enough, a good vigorous impression, such as would serve for enlarging, is at once obtained, but then it sometimes happens that this dark-tinted tissue is not at hand. But perhaps the most useful application of Swan's discovery is the following. In the case of one's negative being broken, it would suffice merely to take a good well-printed carbon positive that you may already have secured from the cliché, and cement this down with indiarubber solution, or some such matter, to a glass plate. Contained immersion in lukewarm water would remove the paper backing, and leave the faint carbon positive adhering to the glass plate. This impression would then be intensified with permanganate of potash, and be capable of yielding in its turn another negative.

ART-CRITICISM.

BY W. NEILSON.

Photography.—If this long preamble have succeeded in indicating the abuse of details in art, the application to photography is self-evident. If the artist be tempted to pander to the prevalent taste of the day, and merge the
central idea of his picture in an undue prominence of unnecessary details, the photographer is naturally still more strongly tempted in that direction, seeing he can render details with a minuteness and delicacy no artist can approach. In turning out his wonderful details, it is especially for him to remember that facility in working is not always felicity in work.

I hold that, as taste is the judgment arrived at by the embodiment and balance of the artistic faculties in the individual, it generally exhibits itself in the community in modes that are far from giving one an idea of perfection; and I must add that the faculties which appreciate beauty and grandeur do not give general evidence of being greatly developed. No doubt multitudes have pleasant associations about the country in the abstract, connected with pastoral idylls, love in a cottage, and the like; but when they stand face to face with nature, they feel no responsive thrill. The blue-domed temple is no temple to them. I shall give one sample, and it is far from being exceptional.

Frequently, sailing on Loch Lomond in a steamer full of tourists, I have observed that not one in fifteen seemed to observe the mountain where they chatted, looked at their guide-books, and enjoyed the locomotion and the hill air; in short, they were “doing” the fashionable in a healthy and pleasant manner; but they were not admiring Nature. Yet these same people would look with delight on photographs of the scenes through which they were passing. The grand details of nature are not as easily believing their magnitudes against the wide spread of shine and shade, were beyond their appreciation; but to see a tree or a rocky island put into three inches, with all the details of twigs and sparkling points brought out in a clear, startling distinctness—ah! that was worth looking at. And sometimes they would have the sense to say, “Photography is a wonderful art.”

The same sort of thing may be seen in Edinburgh any summer day, when Princes Street is crowded with tourists on their way to the Highlands. Few are the glances bestowed on the unique view of Castle and Old Town; many are the heads that gravitate in the other direction towards the shop windows, which, no doubt, are well worth looking at. It is from such as these, who have little or no feeling of the beauty and grandeur of nature, that the demand for photographs full to overflowing with a mass of details has sprung, and they who supply the demand are engaged in a profession which, from a point of view, they have a fine field for their energies; but they need not think they are cultivating an art, or elevating the public taste.

Art does not consist in imitating, but in representing nature—quite a different thing. The artist knows that he cannot imitate nature without omitting her principal feature—the grandeur of her magnitude—and that to give all her details diminished to a petty scale would be a mere caricature, turning the grand giant into the semblance of a paunchy dwarf. He considers how he can represent in a small space some feeling of the unattainable magnitude. How is the dwarfing canvas to give a gigantic effect? He must contrive that the leading features of a landscape shall distinctly传出 from the minor or unnecessary details by enhancing the one and obscuring the other. Knowing the incompetence of art to give the oil of nature, his aim is to pronounce the leading idea of her grandeur. He throws a deep shadow on one part—not that the spectator may imagine something, but that the prominent feature may have its value enhanced by the mantling grandeur, and thereby from which it rises; and he throws another variety of shades here and there, to give a feeling of softness, or refinement, or tenderness, as required by the theme; and thus, whilst he pronounces the idea of the scene by so merging its unnecessary details, he carries us beyond it into the bygone of our impressions connected with the feelings of grandeur or refinement or tenderness with which he has imbued his picture. It is only by thus representing nature that a picture obtains breadth, force, simplicity, and repose, which are essential qualities of art.

The painter has an advantage in his brush that we have not in our noble tool, the sunbeam, inasmuch as he commands his brush, while our tool commands us. But art binds all her votaries alike: they must aim at representations. When the photographer first considered his landscape and got it properly composed—his first great difficulty—he must study it under every aspect of light, and seize the moment when the shades fell most advantageously to enhance the leading features and merge the unnecessary details. He must remember that the success of his picture depends on its shades. Let him get the gradation of shades right, and the lights will take care of themselves. The same rule applies in the studio. Brilliant details, when unnecessary, are the death of art.

Texture.—Texture is one of the essentials of fine art, and, like the other essentials, depends on an innate feeling. It cannot be acquired. It is in art what the timbre of the voice is in music; you may cultivate the voice, but you cannot cultivate timbre. The artists when painting a face to think of the cheek of a peach. Texture gives the peachy softness, the life touch, the completing charm, which cannot otherwise be attained. Sir Joshua's own works show much of this charm, which is not so apparent in those of Sir Thomas Lawrence.

That something equivalent in effect to this texture can be obtained in photography I am in no doubt. I hold with Sir J. J. Clarke that photography is an art comparable in analytical ingenuity than a flesh consistence. The question is how to keep the lens from producing such results in heads of three inches and upwards?

Mr. G. Crompton did me the honour of noticing some remarks of mine on the subject, in an interesting paper read before the South London Photographic Society. He says, "In my experience I have sometimes been on the point of saying, ‘It may be obtained without any developer.'" Perhaps his remarks were intended to apply only to small-sized heads. I have always found the common style of developing in large-sized heads to be productive of anything but life softness, giving a mere imitation of the fibres of the skin. The larger the head the more pronounced must the texture be.

(To be continued.)

THE PRACTICAL PRINTER IN AMERICA. XIX.

CUTTING AND MOUNTING.*

In many galleries the prints are cut as described above, and mounted upon cardboards ornamented with gilt stripes in the oval and square forms, inside of which forms the prints are carefully mounted. Below the mounted photograph the photographer has his name printed in small gilt letters. A print cut oval, and mounted upon one of the oval mounts, has the appearance of having an oval mat over it, with the advantage of having your name printed on it. A great objection to this is that of having to choose the frame at the time of making your choice of picture, so that the check can be made out properly, thus enabling the operator to mark on the negative either square or oval, which means to cut the 4-4 prints square or oval, according to what is marked on said negative. For instance, a lady wanted a 4-4 arch-top, and on

* Continued from page 119.
choosing the frame at the time she decided on the style of print; she chose a square one, and the check being made out properly (having all the particulars on it), and being passed to the operator when she entered his domain, he reserved his part of it, and sent her according to orders upon it, and marked the negative as per check: One 4-4 Arch-top, No.—(of negative). Often the words, cut square, are placed on the negative; but in this case, when the style is an arch-top, it is not necessary, because the print cannot, with taste, be cut any other way.

When the print is to be mounted upon a lithographic mount, the operator marks the negative L. M., and then the printer also marks the same letters on the back of the print before it is toned, being sure in doing so that he marks in the shadow or drapery part of the said print, and the mounter, as she pastes the print, sees the marks, and consequently mounts such prints upon the lithographic mount. If the lady had chosen an oval frame, she would have to have a vignette style of print to look well, and the negative should then be marked (also as per check): One 4-4 Vig., No. — (of negative), cut oval. Of course prints that are printed either in medallion, square, or arch should be cut square, except in a few cases when the prints are printed plain; then they can sometimes be cut oval, if desired.

To those photographers who are not in the habit of this mode of working, the above may appear to be very complicated, but it is so arranged in every well-regulated gallery and where there is perfect system throughout the establishment. It is one of the most perfect ways, as regards system, connected with the orders, that there is known, and it is very seldom any mistake occurs when once the plan is in good working order and if it be followed, this would cause trouble when duplicates are wanted from the negatives, but that is not so, for when duplicates are ordered from frame-photographs (i.e., those photographs which are to be framed), the patrons almost invariably order the same style of frame and print that was before purchased, and the printer is thus greatly benefited, besides no money has to be paid over. Upright prints that are ordered from "old negatives," and when there should happen to be a variation in the style of frame and print, the thinking photographer will readily invent some way to prevent mistakes.

When the prints are to be cut in an oval form, the excellent tool known as the Robinson Photographic Trimmer is indispensable. (See fig. 1.) It does its work so quickly and with ease, and the one can estimate it too highly. It will outwear a gross of knives, and does its work better, without tearing the prints. Guides that can be used with it are furnished at a trifling cost. This trimmer, by the way, is also an excellent thing to use in cutting medallions and masks whenever you may wish to make them. When you are about to cut square 8 by 10 prints, the plate-glass is first laid down on a level bench and the print on it, and upon the print is laid the glass that is used in cutting the print. Adjust this latter glass, and with the knife cut a quick and clean line on it, including the head and close to it. If you choose, you can cut the other sized prints, such as the Imperial and Victoria, by the aid of the shokknife and the proper glasses. I have recommended a shochknife because it is cheap, costing only about twenty cents; then, again, it is better handled than a penknife. When cutting with the glass and knife, place two or three fingers of the left hand firmly yet lightly upon the glass, and cut with the knife in the right hand, cutting around the glass, shifting the elbows a little to one side or the other as occasion requires. (See fig. 2.) The Robinson Trimmer will also answer for cutting square prints with a very slight round corner. There are a great many printers who use the knife altogether in the cutting of the prints, and then, again, there are many who use the shears. I generally use the shears for cartes and imperials, but for larger prints I use the knife.

It may appear to be a small matter for me to write here how you should use your glass and shears in cutting, yet there is one thing which, if observed, will save your cutting glasses, and also save your shears from getting dull so quickly; it is this:

Many persons in using the shears cut down at the lower part of the glass at an angle, so that the blades of the shears run along the edges at the bottom part of the glass-guide, and consequently the glass is very soon nicky, and in a short time some of the corners are broken off, and the shears is worthless. Now this is owing to the style of cutting (or chopping) with the shears, because every time you cut a print you also cut the glass, or try to. You should allow the blades of the shears to fall parallel to that side of the glass at which you may be cutting (see fig. 3), and you will save your glasses, and also prevent the shears from getting dull so quickly.

The rules which will perhaps help the beginner in cutting the prints are the following:—1st. Never have the nose or chin higher than the middle of the print, if the head is of an ordinary size, and the print is printed plain. 2nd. Allow a trifle more space on that side of the print toward which the head is turned, being careful not to allow too much, however, as very often the shoulders suffer by the abuse of this rule. 3rd. If the print is to be cut in a medallion, and the head is very large, it ought to be cut higher up in the print than otherwise, so as to obtain plenty of the body to balance the head. 4th. In cutting out a print, when the figure is leaning on a table, chair, &c., always cut in enough of the accessory to give an air or look of solidity to the base of the print. 5th. Always lay your glass, when you are about to trim the prints, in the same direction as the body is, providing it is not leaning on a table, for then, of course, you must represent the idea of leaning; but when there is no such idea to be conveyed, then trim as before said, so that the body will not appear to be leaning too far forward or backward, and thus give the beholder the idea of falling. 6th. Sometimes by cutting the print so that the person will appear to be leaning slightly, the head and face will be made to look better, and the figure is that of a large Berlin head. Look out that you do not overdo this, however. 7th. If the print is printed in a medallion or arch-top, you should cut it so that there will be as much of the tinted border show on one side as there is on the other, and as much at the top as there is at the bottom, and always cut prints that are printed in either of these styles in the direction that the oval or arch-top may be, and never cut them so that the cut and the oval or arch-top will lay in different directions. To do this you must be sure, in placing on the oval or arch-top for printing, that you get them to lay in the right direction. 8th. If the figure is a standing one, and the whole of it can be cut in the print, then do so, and not
cut in only part of it, as is very often done. 9th. If it is a sitting two-thirds figure, then do not think of such a thing as having the nose or chin come in the centre of the print, as per Rule 1st, but have it come considerably higher up in the print, being careful, however, that you do not get it too high. 1oth. Sometimes there are groups of two, three, four, or even five persons in a carte-de-
visite photograph, and, in cutting out these kind of prints, be sure that sufficient of the drapery on either side is cut in, as the neglect of that will make these outside persons appear very slender, being no balance to the figures; and, for such cases as these, either in the small card or the imperial, we have made the larger glasses as described above. 11th. If the figure is a standing one of a lady (a bride), with a long train dress, and leaning on a chair, then in cutting, not only cut the print so that you will give the idea of leaning on the chair, but cut a very great portion of the dress in, even if the figure of the lady herself is over to one side of the print, for the face is turned (or should be) towards that direction, and you can trim as above, without danger of hurting the look of the print, for, on the contrary, you will greatly improve it. 12th. When the background of the print is one that shows interiors or exteriors, such as the panels of doors, or a set of perpendicular rows of columns, &c., always cut the prints so that these uprights will be parallel to the sides of the trimmed print, and the cross-panels parallel to the base of the print. This kind of a background is more often found in the large prints, more especially so when the "Bennand Backgrounds" are used. 13th. In standing figures, very often the place where the floor meets the background comes in sight when the print is trimmed, and in such cases you should always cut the flooring parallel to this line; and, in the great majority of cases, if the position is properly arranged, the figure will lie in the proper proportion as observed by the simple rule. 14th. Do not, when cutting prints, try to see how quick you can cut them, but how well, for a dozen well-trimmed prints are worth more than a hundred indifferent ones. First try and see how well, and then, after you have learned that, then see how quickly, you can cut them.

The advice and instruction which we have endeavoured humbly to give in this chapter is intended for those persons whose experience at printing has not been so extended as ours, and it is emphatically for such persons that we have written the above, and not for learned printers.

THE ART OF POPULAR ILLUSTRATION.

BY HENRY BLACKBURN.*

It was well remarked lately by Mr. Waterhouse Hawkins, in a paper on "The Graphic Method of Teaching," that through the pictorial system the mind receives impressions with the least effort, and in the quickest way, and that the graphic method was the true way of imparting knowledge. Are we, then, in the matter of giving information imparting knowledge through the medium of illustrations, adopting the least perfect and least effective methods? I venture to say that in the majority of cases we are doing nothing of the kind. We have pictures in abundance which delight the eye, which are artistically drawn and skilfully engraved, but in which, in nine cases out of ten, there is more thought given to effect as a picture than to illustrating the text. This question was discussed by the members of the Society of Artists about a month ago. Speaking of the system of book and newspaper illustration then and in vogue, it was argued thus:—

"The great want at this time is a simpler and better form of illustration for novels, tales, magazines, newspapers, and for all literature of the butterfly kind. The present system is too cumbersome, too costly, and too absurd to last. It is an absurdity, for instance, committed every day, to give an elaborate drawing of furniture made out to the exact square of the page, for the purpose of expressing a lover's devotion, and almost as unnecessary to make a careful view of Hyde Park as the groundwork for a pen." To standard works, and those of high artistic aim, these remarks do not, of course, apply.

The objections pointed out in the Athenæum to the carefully shaded view of Hyde Park, and to the imaginary drawing-room, were well founded. That for moderate and low-priced economy, such details can seldom be well engraved. 2. That they are generally untrue. 3. That the space occupied, and the cost incurred in production, tend to decrease the number of illustrations, and to a lack of variety.

After expressing a belief that the time will surely come when we shall look back upon the present monotonous method with considerable amusement, and upon a book or newspaper that is not illustrated as an incomplete production, Mr. Blackburn proceeded: Let us consider, shortly, the means at our command, both artistically and mechanically, and see what are some of the possibilities in illustration.

First, in the daily press. A "special correspondent" is someone who, to what is called the seat of war, or is stationed in some remote country, to give the readers of a newspaper the benefit of his observations. What does he do to express himself most clearly and quickly?

In the imperfect, clumsy language which he possesses in common with every Minister of State and national school boy, he proceeds to describe what he sees in a haphazard, when two lines would tell the same story much more efficiently and successfully his meaning pictorially. I think you will admit that our ordinary-written language is clumsy, when I remind you that in order to provide the copy for a newspaper correspondent's letter such as we see written in the Times every morning, the point of the pen has had to travel over a distance of more than one hundred feet! This is the actual ascertainable measure of the average letter, which tells us what the ups and downs, cross and dashes of an average letter as it arrives from abroad; and yet we hear of letters "written under fire," "written on a drumhead," "in the saddle," and under the greatest difficulties when rapidity of record is everything. By systems of shorthand the time occupied in transmitting intelligence by letter is reduced, but the pictorial method of communication should continue to suffice us, and really as simple forms will soon be transmitted by telegraph.

Think what interest would have been added to Dr. Russell's letters in the Times, from the Crimea, if it had been possible to have inserted here and there with the type a line or two pictorially, or even a little diagram of a movement or position. It may be said, "we had our illustrations in the newspapers ever so long ago, but now sketched by special artists." True, but the illustrations took time to prepare, and the reader of these vivid letters had "gone on to something else." The pictorial record should have been simultaneous with the verbal—the picture was wanted when the letter was read. Again, in time of peace there are many events of interest and scenes passing before the newspaper correspondent's eye, which are not adequately described in words. In every city or town, in every place, there is some leading feature, architectural or natural, that gives character to it; and it would add greatly to the interest of letters from abroad to have them headed sometimes with sketches. On important occasions, and for special subjects, the foreign correspondent would be accompanied by an artist trained in the fine arts, who could draw, and sketch himself. He could present to us often in outline the aspect of a street, or the curve of a line of hills on which some event of public importance was taking place; he could indicate the shape of a church spire, or a new bridge, and the plan or diagram of many objects of interest. If he could not do this actually with his own pen, he could often get it done, or transmit photographs of it, on which it is now possible to make a little outline in relief to print with the type in six or eight hours. The point is, that the sketch

PHOTOGRAPHIC NOTES.

BY THE REV. F. L. SADLER.

Durable Sensitive Paper.—If you add to a silver printing bath some nitrate of alumina, the paper that is sensitised thereon will keep its whiteness, and it will never assume that yellowish tint which is generally observed upon stale albumenised paper, formed from the organic matters of the paper. You may add as much nitrate of alumina as nitrate of silver, if you like, or only half the quantity of the former. As a means of preservation, this method has no advantage over others that have been proposed, but it has several additional qualities that may be mentioned. For instance, the nitrate of alumina solutions of albumen which yield an image in a silver printing bath do not deposit any organic matter in the bath, and therefore the latter does not become darkened as is the case usually. Again, the paper treated on an alumina bath does not harden so much on drying, and it is not so liable to curl up at the corners, as when the ordinary bath is employed; this is a consideration of some moment, as it will lie flatter against the negative. The drawback to the process is, that the prints turn so slowly in the gold bath, so that it becomes either necessary to allow the pictures to remain in the solution for a longer period, or to employ a stronger bath.

Bromised Collection.—The alkaline developers that have succeeded well except with a little iodide of silver, for with the result obtained. Bromide of silver, unfortunately, however, forms very slowly in the exciting bath. It is for this reason that one is obliged to augment the amount of soluble bromide in collodion, and in like proportion the nitrate of silver in the negative bath. In the ordinary process of iodide of silver forms much more rapidly; I think this is due to the difference in the bromide of silver forming a very close and slightly permeable film, which retards the transformation of the underlying bromide. I have tried many ways of making it more porous, and therefore more easily penetrated, and have succeeded in the matter by adding a little glycine to the collodion. By allowing a plate covered with a film of this kind to remain in the sensitising bath for (say) five minutes, a film of bromide of silver is deposited on the plate and has a uniform character, and such as will yield a capital image. Ten to twelve drops of glycine suffice for every hundred c.c. of collodion.

To this quantity of collodion it is well to add three or four drops of alcohol in which a little nitrate of silver has been dissolved. After the lapse of some time a slight excess of nitrate of silver is precipitated in the state of bromide, and the collodion is deposited on the plate, and the transparency which it keeps indefinitely.

Collodio-bromide.—The collodio-bromide process has not yet realised all the hopes which its disciples entertained. Very simple at first sight, the process became quite embarrassing by reason of the care to be exercised to keep the collodion from the light, and also because the liquid had a tendency to become poorer in bromide of silver, which it deposited, and thus the solutions of bromide were continually altered. I have found that by adding a little acetic acid to the collodion, the precipitation of the bromide of silver is retarded, and sometimes even completely arrested. Acetic acid is one of those products of the decomposition of ether exposed from time to time to the atmosphere; and if you often find differences in the properties of such and such a collodion to hold bromide of silver, the ether is probably to the more or less decomposed character of the ether contained in it. Acetic acid employed in this way will be a resource for such amateurs—rather few, I fear—who desire to make use of collodio-bromide. If photography upon glass had made its debut with this process, there is no doubt the process would have been improved by separating the two products, and employing them as is done at the present moment. (To be continued.)
THE LATE PROPOSED ALTERATION IN A LAW AT THE PHOTOGRAPHIC SOCIETY.

A curious illustration of the danger of a litigious spirit taking possession of individuals or communities was furnishing at the late meeting of the Photographic Society, when a proposed minor alteration in a law was met, not with a consideration of its expediency, but with an astonishment that it should be a strained application of an existing law. And the most remarkable feature in the case was, that whilst nothing need have been more simple than the case as it stood, nothing more obvious than the actual power of the meeting to make the alteration, if, on consideration, it were found expedient to do so, all this was lost sight of in the spirit of litigiousness which suddenly bunged up and enveloped the real question in the smoke of the discussion.

The facts are simple. In the laws of the Society a clause exists, which has existed from the beginning, to the effect that no member shall have the "privilege of voting on any occasion unless he shall have paid his subscription for the current year." This clause has, however, been practically a dead letter, and has no questioning as to payment was ever raised previous to voting. When, however, twelve months ago, a requisition was sent to the Council calling a special meeting to make changes of a revolutionary character, and when it was found that amongst the names appended to the requisition was one, at least, assuming membership without ever having paid one penny to the Society, either of subscription or entrance fee, it was found desirable to put the clause in question in force, and make payment of all dues to the Society a condition of voting. Until the annual meeting just past this was the only occasion on which the clause was ever enforced. The late annual election involved new machinery: the Secretary found this law in existence, and having no instructions, took the obvious course which presented itself, namely, sending to each member a card circular with an extract from the enactment in question, and intimating that a balloting paper would be forwarded on receipt of the amount of subscription due. The receipt of this circular gave offence to many, and the operation of the law, it is probable, materially limited the number of votes returned. Mr. Hooper was anxious to secure a modification in this clause in order to avoid trouble, and having had the due notice in time for a motion at the annual meeting, the Chairman at that meeting announced that the next meeting (that held on the 9th inst.) would be made special for considering Mr. Hooper's motion, of which he then gave due notice; and the notice was duly printed in the Society's Journal. The meeting having been made special, at the close of the last ordinary proceedings, Mr. Hooper proposed his motion, which was simply to the effect that no member should be permitted to vote unless he paid his subscription for the past year, instead of the current year as the law now stands, the object being to avoid the inconvenience of disqualifying a member for non-payment of his subscription within a few weeks of its having become due.

The wisdom of adopting such a motion is, of course, open to question, and much might be fairly said on both sides. We are strongly inclined to endorse the views expressed by Mr. Bird, that in the affairs of a Society, as of a nation, taxation and representation should go hand in hand, and any payment from the pockets of the members of the officers of that year; although, at the same time, if there were no other method of meeting the difficulty, we believe that many would probably acquiesce in the motion as a matter of expediency. But in the debate which followed, the rectitude or expediency of the motion was almost ignored. The motion was no sooner proposed than Col. Wortley objected that the meeting had no power to deal with the question, because, according to Law XL, no alteration could be made in any law except at an annual meeting or special meeting, and a special meeting could only be called by the Council. He further objected that a notice to every member was requisite of the intended motion. But in truth the meeting was a special meeting, duly appointed by the President, who for such purposes has the right of calling the representatives of the Council. It had been most fully and duly given in the organ of the Society, its own Journal, sent to every member. Col. Wortley contended that notice should be by letter; but this is an interpretation of his own which finds not one word of warrant in the laws. Another point as to the legality of meeting for such business was curiously overlooked: a special general meeting could be adjourned, in die in diem at the chairman's pleasure; and the chairman on this occasion practically did no more than adjourn the business meeting, then in progress, for a month, to permit of the due notice of the proposed motion being given. Thus it will be seen the vision of cumbersome machinery called up was doubly baseless, and unsupported by any ground of fact. The President answered, however, that the situation was this: the provisions of laws which had been made during the period of his absence from office, and which, with a touch of human nature (pardonable, if slightly amusing), he seemed not unwilling to believe were so obstructive as Col. Wortley described them to be. Mr. Stillman, ever ready as a Freelance to join in any fray, at once endorsed Col. Wortley's objection to the legality of the meeting and the President's comment on the law, which he stigmatized as obsolete and impractical, innocently overlooking the fact that the law in question was, with the exception of the final ratification clause, copied verbatim from the cumbersome and prolix code of twenty-five laws and seventy-six clauses recommended by the committees of which he himself was a member! The law, it is true, might be simpler in construction, but there could not be a doubt as to the meaning of its provisions in the mind of any reasonable man.

Turning for a moment, however, from the question of construing laws, let us glance at the usual practice. Where an actual doubt exists, it is customary and wise to seek its solution in precedent. The custom of the Photographic Society—which has always had similar enactments, but still more stringently expressed in relation to the alteration of laws—when any similar modification in the existing code has been found desirable, has been for the chairman to announce at one meeting that the next meeting would be made special for such and such a purpose, due notice in the Journal has followed, and the desired alteration has been effected at the termination of the next monthly meeting made special for the purpose. The Society has, in short, carried out precisely in all respects similar arrangements to those made at the last meetings for
Mr. Hooper's motion. This has been the general precedent. But let us cite a special instance which possesses a singular pertinence to the present question. The difficulty which Mr. Hooper's motion attempts to meet arises chiefly out of the fact that the Society's financial year commences in January, whilst its annual meeting does not take place until February, thus making the subscription become due a month before the annual meeting. At one time the financial year and the annual meeting were at the same time, but for certain reasons it was deemed expedient a few years ago to change the commencement of the financial year. Now, this very change in the laws was made at just such a meeting as that held on Tuesday, week, announced in precisely the same manner, and with precisely the same kind of notice to the members. But there was one other objection raised by Col. Wortley. The chief difference between the present enactment as to the alteration of laws and that in the old code is a provision against revolution in the Society without time for deliberation; and a final clause enacts that the ratification of any change in the laws agreed to at a general meeting shall be by ballot of the entire Society. Col. Wortley objected to invoking such cumbersome machinery for a matter about which no objection seemed more natural and sound enough; only it was singularly inopportune. Col. Wortley and every one else joining in the discussion seemed to forget that the code of laws itself has not yet undergone that ordeal. The laws passed during last session have not yet been ratified by a ballot of the whole Society. The delay in carrying out such a project was intended to meet just such contingencies as the present. When the new code was somewhat hastily prepared, it was foreseen that minor points might easily be overlooked, and when the laws were presented to a special meeting called for the express purpose of receiving them at the end of the session, it was distinctly announced from the chair that they would very possibly be found capable of revision, which would be considered at the next annual meeting. It would manifestly have been wise not to press for their final ratification, by the ballot of the entire members, until after opportunity of revision had been made available to every member who might consider it desirable.

As Mr. Hooper's motion was passed subject to further consideration of the legality of the proceedings, it is probable that it will acquire force and must be treated as the present law, as we apprehend, scarcely necessary. All the objection complained of might be avoided, without altering the law, by following the precedent of other learned societies. It would be simply necessary—instead of sending a note to members in arrear, informing them that a ballot paper would be forwarded on payment of such arrears—to send to every member a ballot paper, with a circular of instructions stating the law on the subject. All ballot papers duly sealed could be forwarded, together with the amount of subscription, to the treasurer, who would hand the sealed document to the scrutineers. We need not enter into further detail as to the machinery here; it is sufficient to indicate that a mode exists whereby payment of current subscription, as a condition of voting, can be carried out without inconvenience or offence.

SPONTANEOUS DECOMPOSITION OF PYROXYLINE.

In a recent letter to our Philadelphia contemporary, Dr. Vogel raises the question whether photographic pyroxylne is liable to spontaneous combustion or not. He says:

"A high judicial court has recently raised here the question if photographic cotton is subject to spontaneous combustion or not. A merchant forwarded a package of gun-cotton (wrapped in paper) by mail, and the package exploded on the way, causing considerable damage. The merchant had to appear before the court, as by our laws it is forbidden to forward articles by mail which are subject to spontaneous combustion. An expert, who is not a photographer, but an apothecary, states that gun-cotton very readily explodes by spontaneous combustion; and this dictum causes, of course, much surprise. Probably the apothecary mistakes the cotton used for colloidion for the cotton used for blasting and gunnery. Both kinds are absolutely different; the one is not likely to explode, the other is. The one explodes with great violence, the other without; the one dissolves in alcohol and ether, the other not; the one used for photographic purposes contains a lesser amount of nitrogen than the other. These differences are unknown to many chemists, or they do not take them into consideration. Unfortunately, most of our learned chemists do not trouble themselves much about photography; so I read recently, in a very good new hand-book of chemistry, that iodide of silver is reduced by sulphate of iron, which is absolute nonsense.

"In regard to colloidion cotton, I have observed circumstances under which the cotton would not have escaped combustion if it was at all subject to it. I have received specimens from England, France, and America; they are accessible to my school, who are very particular in their treatment. Some samples are wrapped in paper, others in bottles. One sample, packed in a tin box, was exposed for months to a hot summer sun. In short, the cotton has been exposed in every way, and I have never heard of spontaneous combustion. I do not hesitate, therefore, to declare colloidion cotton not subject to spontaneous combustion, and the explosion in question was probably due to carelessness of the post-office officials, who likely smoked.

The question raised is one not free from difficulty. Photographic pyroxylne, whilst undoubtedly a very different body in many respects from gun-cotton proper, is so nearly allied to it that in the manufacture of either there is apt to be produced a trace of the other. The enquiry into the Blowmarket explosion some time ago showed that much uncertainty still prevails as to the possibility of spontaneous explosion in gun-cotton, the general tendency of the evidence being to prove that imperfectly washed gun-cotton is readily liable to such a result. In like manner we have known pyroxylne of a perfectly soluble character decompose spontaneously; not, indeed, so as to cause combustion or explosion, but sufficiently to cause the solution in red nitric acids, leaving a little semi-liquid gummy residue. The danger of such a result with carefully prepared and well washed pyroxylne is very slight; but it exists, and is sufficient to suggest the necessity of care in storage. The danger is greater if it be kept closely packed and protected from the atmosphere. If kept loosely packed in tin boxes or glass jars, with loose covers, the danger is reduced to a minimum. The possibility of coming into contact with sparks of fire or a lighted cigar, common sense will dictate should be avoided.

ON PHOTOGRAPHIC STATUS.

BY EDWIN COOKING.*

My name having been mentioned in a paper read by Mr. Hooper at the January meeting of the London Photographic Society, implying that I was the first, or nearly so, who brought before the notice of photographers the subject of some distinctive mark being conferred upon them, probably a few remarks from me on the subject at that time may not be out of place at the present moment. In 1867, when I read before this Society my paper, "A Suggestion for Raising the Status of Photography," I had arrived at the fact of the inability on the part of the public to properly distinguish between those who practised photography mechanically, and those who brought cultivated
taste and artistic feeling to bear upon it; hence I thought
that some extraneous expression of opinion other than that
of the photographer himself, or the public, would meet the
difficulty. The idea I endeavoured to illustrate was this, that
some properly-elected body should possess the power of
determining the fitness of those who submitted themselves
to such a tribunal, and also to grant some sort of certificate
to such fitness. The immediate result of this, I thought,
would be that those who did not consider it necessary to
avail themselves of this examination must be content to be
certified by no means, or, at all events, outside the ranks
of qualified operators.

I advocated two degrees of merit—the one being, as I
have just mentioned, universal in its application, attainable
by all who evinced capabilities for photographic work, both
in the matter of artistic taste, and in chemical and optical
knowledge; the amount of proficiency necessary to gain
such certificate to be set forth from time to time by the duly
elected examining body. These photographers would be in
position something like the medical profession, who obtain
the title given by the College of Surgeons, or the ordinary
chemist or druggist, who obtain certificates from the Apothecarists' Company or Pharmaceutical Society, without which
any one who appeals to the public for patronage would be a
quack; in short, not a fit and proper person to undertake
the practice of his calling.

I then further advocated the possibility of a much higher
grade of examination by a mixed tribunal of artists as well
as photographers, to possess the power to grant some
honourable title to such as had produced great results, the
number of such to be limited; and this, consequently,
would inspire emulation throughout all ranks of our
profession.

I never for one moment entertained the idea that the
simple payment of a subscription to any society should entitle
the person doing so to any distinctive mark. My object was
the gradual raising of professional status, by having some
defined standard of excellence in all branches established, so
that every photographer could see how near, or far from,
the desired position of honour he might consider himself.
How far the last seven years of the history of photography
would have justified such an order of things, and whether
the time is ripe for such an institution, may possibly now
be the subject of thought and discussion.

It will, I think, be granted by all who give any thought
to the subject that, without interfering in any way with the
liberty of any one person who thought fit to venture upon
gaining a living by entering our profession—at the same
time it is not to be supposed that a man without a taste
marvel—its true friends must see the necessity of laying
down some laws or rules for the future working of the same,
and the introduction into its ranks of more properly-
educated, and, consequently, more qualified, exponents than
has hitherto been the case.

But the germ of what I have been suggesting, I think,
already exists, inasmuch as the Photographers' Benevolent
Association, just established, must in its working enforce
some sort of qualification before it could with justice dispense
any of its funds; so that we have only to build up a ladder,
as it were, of gradual ascent to arrive at the pinnacle of
what I think, if once established, would prove to be
as valuable an aid to the progress of photography as
anything that has hitherto been done towards that object.
It must be admitted that, supposing such a tribunal had
existed seven years ago, the necessary scale of qualifications
must have been raised much higher at the present day,
when we see the marvellous strides that photography has
made in its pictorial element—by which I mean the active
cultivation of latent artistic feeling, the daring efforts to
regulate light and shade, and the greater attention given to
the disposition of lines, involving the study of composition,
showing that there has arisen a woeful loss of development
of power evincing design and thought.

All these results, I cannot but think, point to the fact
that we have approached the time when such a matter as
that I hinted at seven years ago may now be duly weighed
and pondered over.

So far we have considered the advantages of some dis-
tinctive title in favour of the public or those who benefit
by the advanced photographer; but something else remains
which should receive the earnest attention of all who have
felt the difficulties arising from the uncertain status, or
want of assured defined social status, that of late has forced
itself upon those who do not like to realise the possibility
of any one looking upon as one's shopkeeper, simply selling
a manufactured article, whilst the other half exercises and
cultivates some higher mental thought and power than is
usually considered necessary for those who merely buy and
sell.

I take it, then, at the moment, the impetus which this
subject ought to receive must spring from the desire to raise
and elevate the author and composer of pictorial pro-
duction far above the more disposal or supplying of the
same, which really only should be supposed to exist as a
secondary matter.

If, then, the cultivation of latent artistic tendencies and
consequent higher phases of productions have brought
about a desire to have some distinctive marks conferred,
whereby the results of cultivated mental and elevating
feeling and taste for good works in art and science should
not only be distinguished from what is simply mechanical,
but should meet with a reward both personal and social (which many would so deservedly be entitled to),
nothing should stop the hearty co-operation of all those
who by the power of their names can put the machinery into
motion for such a consumption.

I do not take upon myself to make any practical
suggestion relative to how all this might be done. I
simply once more sound the key-note, so that all those
who sympathise will respond and take up their parts.

HINTS AND SUGGESTIONS.
BY D. H. CROSS.

I have tried varying the strength of silver solutions for
genatives, and have been surprised to see the extent of
variation that can be successfully employed, and that, too,
without essential change of the collodion, developer, or
manipulation. Forty grains of nitrate of silver is the
maximum, and fifteen grains the minimum, to the ounce of
collodion. Both this is more than would be required in
succession, on all kinds of work, without injurious change,
except that common to all baths from accumulation of
alcohol and ether. For a standard strength in the studio
I should not exceed thirty grains to the ounce of water.
First. Because less injury results to the plate if it remain
in the solution a few minutes after it is sensitised. Second.
A longer time may elapse after the plate is, placed in the
plate-holder before it is developed without the appearance
of the annoying matt stains, which are so common in the
hot season, when forty or forty-five grains are employed.
These experiments have proved to me that much greater
latitude may be exercised with our bath formulas than is
generally supposed, with equally as good results.

Iodising the bath I consider not only unnecessary, but
also injurious, since the strength of the solution does not
exceed forty grains to the ounce. Having tested this
matter often within the past ten years, I have abandoned
the practice entirely. If let alone the bath will take care
of itself, in this respect, from first to last, while nothing
desirable is sacrificed; pinholes are thus banished effectu-
ally by removing the cause, viz., excess of iodide of silver.
Cleaning the plate with spirits of ammonia, and then
mercury is better to reduce the proportion of iodide from five
to three and a-half grains; of bromide, from two to one and
a-half grains, to the ounce of plain collodion, if the bath is
thirty grains or less to the ounce.

* Read before the N.P.A. America.
The practice now becoming general, of dipping the plate in the bath, film side down, I strongly recommend; by so doing, uniformly clean work may be made, without the formation of that scum; I find it only after evaporation, and avoid frequent evaporation, by leaving the cover of the bath open, so that the fumes of alcohol and ether may escape spontaneously.

A cover for the bath should be made so that it will allow these fumes to escape, and exclude the light and dust. Here is a chance for a little inventive genius. Having had but few years to try several processes for producing “large work,” I have concluded that it is much better and easier made direct when the best appliances are at hand, and the required size does not exceed 20 by 24.

For small children, or very restless subjects, box-light copies, &c., enlarging processes are indispensable, of course; still it will pay many establishments to provide themselves with the improved instruments for large direct work. Life-size bas-reliefs may be made with an exposure of one to one and three-quarter minutes very satisfactorily as plain photographs. Children, three-quarter length, on 18 by 22 plate, with ten to twenty seconds’ exposure, when circumstances are favourable. During exposure of the plate, I have often succeeded best by facing and engaging the sitter by conversation, or other means that judgment and experience suggest at the time. Instances are not uncommon where the best results are obtained by keeping the sitter unconscious of being in the “dentist’s chair” — by not informing “when the tooth is to be drawn.”

Let us not degrade ourselves or our profession by trying to talk off faulty work, or by reducing prices, but bear in mind that good work will find its way out of the unskilful hands of the amateur. Many people to-day can readily discriminate between the good and the bad, and he who adopts this principle will surely gain by it in the end. Let us not content ourselves to practise our art mechanically as artisans, but think, study, and earnestly strive to be artists in a proper sense; and see to it that we elevate our profession to a higher standard, if not, indeed, to fine art itself.

The sky-light is an abiding faith in the canon of photography, that it is destined to be the art (if it is not already) in the realm of portraiture, at least. “Last, but not least,” let us avail ourselves of the light the old masters have thrown upon the subject of art culture. Many very valuable works may now be obtained upon this hitherto neglected subject.

HOW TO LIGHT THE SITTER.

BY H. W. BOOZER.*

Among the changes in photography during the past few years, none have been more noticeable than the methods of lighting our models. For a time “posing” the sitter was the all-engrossing photographic topic; but the disposition of light and shade, and the best means to effect the desired object, is now the operator’s great work.

The sky-light of our venerated fathers of the art was too littley what its name implies, and is justly censurable for much fault-finding from the unlucky wight who “vegetates” beneath. The sky-light is chargeable with much of the ill-health peculiar to photographers as a class. It gives him an atmosphere of great extremes; a furnace of heat in summer, a frigid zone in winter. In low rooms, and especially in tents and cars, the breathing is done in a strata of the most impure air, most of the time overheated, and this, of course, is more the time than the floor, enough of itself to induce permanent ill-health. As a general thing, the sky-light is too high and difficult of access; it is almost an impossibility to keep it clean; the occupant beneath abiding in the delusive belief of a large area of transparency, under-times, consequent on the large surfaces of dirt and stains generally invisibly spread out between the sitter and the arctic power he so nervously wooes. In wet weather the “light” leaks more or less, this is more than a occasion; but “what can’t be cured must be endured,” and after soaking cameras, back-ground, carpets, &c., a few times, they are, with exception of carpet, carefully placed out of danger before the storm, and kettle, pails, &c., take their place. Very few skylights there are but what are affected with this malady to a greater or less degree.

Let driving down on your lens and into the room, making false lights which bewilder and confuse, deranging the perceptions during the limited available time spent in the sitting, rendering the impression, on examination, a defective one. It is seldom the sun does not reach it more or less of the time, and the changes are so rapid that timing is much of the day difficult, to say nothing of the intricacies involved in the production of effects of light and shade, where the fundamentals with which to do are never twice alike.

Did you ever work a sidelight? If not, you would be astonished on trial at its availability for photographic use, and at the effects that can be obtained by the use of “cut-offs” and reflectors. A marked sky-light effect can be obtained by a white reflector stretched from the top of the studio to the front of the sitter, or to a reflector on one side of the sitter. An intercepting “cut-off” prevents over-lighting on the one side, and a reflector on the other mollows the shadows into half tone. With care the eye can generally be rendered pure and beautiful without false lights, or at least the latter so subdued as to be very slight, and always made good by lightly retouching the print. It is an absolute change in this direction that will convince the photographer under the influence of that potent word “sky-light,” bequeathed us by the fathers in the art, whose ideas of light were entirely satisfied by a hole in the roof facing north. But when it is remembered that one of the world’s best operators has attained a wide spread reputation in Montreal by the use of high sidelight only, the latter is certainly worth a careful trial by the photographic truth-seeker.

The great masters in the world of fine art, the men of the past who through their works will always live, have given us as the proper lighting of the portrait a small volume of light falling from some distance on the model, at an angle from above of forty-five degrees. It should be the work of photography to produce just this effect in detail, by the means available to it. If the light falling in this way is used, the result would be vastly different in photography from that in nature. In the one instance the light is gently modulated, giving fine and clear half tone, and great detail even in the deepest shadow; while in the other there is over-lighting on one side of the face, which abruptly turns into the deepest shade, obliterating the half tone in both light and shadow, and making it the freest thing possible from that which was seen, and an entire failure in an artistic point of view.

It is learned by photographic experiment that the diffusion of light over the face increases in proportion as the model nears the glass surface, and decreases with distance; also that the actinic power of light increases in the same geometric proportion in the same way, and vice versa. Putting these facts together, it is evident that the best effects are attained by bringing the model near the glass, and the fact is proven by so doing. Experience in demonstrating this has brought low skylights in fashion, and many galleries now lessen distance by false raised floors, which thus bring the sitter nearer the glass surface, and so much improve the quality of the work as well as shorten the time for sittings.

It is evident that a light built at an angle of forty-five degrees would not be much photographically unless it were placed at an extreme elevation, from the fact that the light from the sky is more powerful than that from among the

* Western Photographic News.
dark objects on the earth’s surface. And it will be found that the inclination of the glass should be two-thirds in a vertical and one-third only in a horizontal direction, on the second floor of a building. It should be about nine by ten feet only in size, the longest up and down. Can be made in two sashes, and thus be self-supporting. The room should be nine feet in height at the upper portion of the light. The sash should reach within twenty inches of the floor.

By the general use of a tissue paper intercepton on the light, and a small reflector the further side of the subject, any effect conceivable may be obtained. While detail is exquisitely fine throughout, the picture will also be vigorous and brilliant, the prominences and high lights being brought out finely by the seeming play of a flash of light over the face from the right angle above and forward.

As regards direction, a north light obviates the use of curtains, which must be used more or less at times from any other point of the compass; the objection to it being that it is weak at a time of day when much of the custom comes in late in the afternoon. In this respect a west light is available, when it is in full consideration that so much cloudy weather is encountered, one is usually tempted, after trial, to curtain during sunlight, and use a west or south light. An east light is essentially a north light for much the largest proportion of work that is done. All who have experimented know that the actinic quality of the solar ray is the same from side to side to side, and that it is its right use only that will produce good results.

After twenty-three years’ experience with almost all kinds of both sidelights and skylights, it is the opinion of the writer that the above-described light will be in the future the model one of the art photographic; and among the reasons for this belief not the least is the fact that the history of photography, especially during the last few years, shows that the practice is working in this direction as fast as a change of such a nature, involving as it does such great difficulties, will allow.

HINTS IN ENLARGING.
BY A BELGIAN SUBSCRIBER.

I know that it is the custom to impart to brother photographers any little information one may possess, or any what you term in England a "dodge" which may have been successful. My plan of enlarging photographs may possibly be worth noting, and for this reason I have jotted down a few particulars.

The picture to be enlarged, whatever it may be—whether a carte-de-visite or other format—previously to being set up in its place, is marked on the margin with a few black dots, which I find aid one materially in the operation of focusing.

The collodion I employ is any kind that will work well for wet plates, and, as soon as my film has been sensitized in the silver bath, I wash, to remove all the excess of silver about it, and then cover it with a mixture of—

Glauber’s salt ... ... ... ... 1 part
Water ... ... ... ... 1
Albumen  ... ... ... ... 1

The exposure I give varies from one to two hours, according to the size of the picture. I operate in a good light, and, if possible, I reflect upon the object the sun’s rays by means of a mirror.

The development is proceeded with as if one had to do with a dry plate, the exposed film being put into a horizontal dish containing an alkaline developer, the formula of which has frequently been published. I intensify generally with a four per cent. solution of bichloride of mercury in water, and ammonium, the image being well washed after the application of the bichloride. I fix in the ordinary way.

CITRIC ACID.

Dear Sir,—Will you allow me a space in your News for a few remarks as regards citric acid. Citric acid, as we know, is imported from the West Indies, and, as it comes so far, is liable to undergo decomposition on the way. On this account it is very advisable for the photographer to prepare his own. It is very simple, and easily managed. Take ten ounces of expensed lemon juice and boil for fifteen minutes, then add to it, when cool, the whites of three eggs, and stir the mixture so that the albumen is mixed with the juice. Boil again, stirring all the while, and allow the coagulum to settle. When cool, filter the sour liquid, and boil again, adding to it, gradually, powdered chalk as long as effervescence is produced. Citrate of lime is now formed, which is but sparingly soluble in water. The dark coloured mucilaginous liquor is filtered off, the residue is well washed, and afterwards decomposed by a quantity of sulphuric acid, the same weight as the chilk which has been added. The sulphuric acid is diluted with seven times its weight of water until the citrate of lime is completely decomposed. By filtration the citric acid is separated from the insoluble sulphate of lime, and is afterwards evaporated until a pelllicle forms it, and set aside to crystallise. The dark coloured crystals are removed from the supernatant liquid by a strainer, and again dissolved in pure water. The liquid is again evaporated as before until the formation of a pelllicle takes place, and set aside to crystallise. By repeating this operation two or three times the crystals become quite pure.

Asking pardon for trespassing on your valuable space,—I remain, dear sir, yours truly,
C. H. P. Varnum.

Grafton, Underwood, Kettering.

NITRO-GLUCOSE.

Dear Sir,—In the years 1865-6 I was conducting a course of experiments with nitro-glucose, having been led to do so from an article in your paper, as to its uses in the process of printing out enlargements by the aid of the solar camera, by Dr. Van Monckhoven. Finding it difficult to procure, I set to work to make it myself, and, like friend Noton, after repeated failures, succeeded. Dr. Van Monckhoven’s instructions were insufficient, as I believe I proved at the time. After making a few ounces, and finding it very difficult to eliminate the acids, I applied to Messrs. Hopkins and Williams for a sample, which they kindly supplied, and having occasion to go to Newcastle I saw the late Mr. John Mason and his partner, Mr. Joseph Swan, to whom I detailed my experiences, and obtained from them a sample that they had kept in a bottle for some years. On my return I tried all three samples, and had the gratification of finding my own manufacture the best of the three. Unforeseen circumstances stopped my experiments, and from that time to the present I have not resumed them, but feel inclined to do so this year.

My object in addressing these few lines is, that they may reach the eyes of Mr. W. B. Bolton, who wrote two able articles on this product in August, 1874, and also Mr. Noton, who has detailed his experiences before the Manchester Photographic Society last month, and that both these gentlemen will favour me with a sample, with full particulars as to its age and character. At some future time I shall have much pleasure in detailing my experiences with this substance. I remain, dear sir, yours truly,
65, Cannonbury Park South, N.
George Hooper.

THE BOUDOIR AND IMPERIAL PHOTOGRAPHS.

DISEASES OF PHOTOGRAPHERS.

Sir,—The introduction of any novelty in order to stimulate photography will be welcomed by all engaged in it professionally. The "Boudoir" portrait, now, I may pre-
name, fairly launched, will no doubt take, and the "Impe-
riri of the Mr. F. Pugin," but I would call your attention to the  
"Imperial," of Mr. Robinson, referred to in the News of  
September 25th, 1874. Would it not be advisable to com-
municate with those gentlemen, and consider the size under  
such a title, and so secure uniformity, as also whether this  
size had not better be circulated under glass, or framed?  
No one is better able to undertake this matter than your-  
self, and I hope you will see your way clear to do this, that  
frames and models can be made to this size also.

I was much interested with your remarks upon the health  
of photographers, as also with the letter of "A Physician."

The fresh air will do much when it is possible for  
photographers to take exercise, and in addition to this, let  
me again recommend the Turkish bath, which I know from  
experience will draw from the system the chemical that so  
insidiously permeates it.—I am, dear sir, yours very  
truly,

[The size which Robinson and Cherrill designate as  
Imperials is, so far as we remember, 10 by 8, and is issued  
under glass ready for framing. The new style introduced  
by Mr. Lewis under that name is expressly intended to avoid  
the necessity for glass, and is really intended for placing  
in an album, as are all the styles issued with narrow margined  
mounts. When this becomes really popular and even popular  
under a special name, it is probable that the name will cease to be used to designate something else.  

SOUTH LONDON PHOTOGRAPHIC SOCIETY.  

The usual monthly meeting of this Society was held in the  
Hall of the Society of Arts, on the 11th inst., the Rev. F. F. STATHAM,  
M.A., presiding.  

The minutes of the previous meeting having been read, Mr.  
Vernon Heath was elected a member.

The Honorary Secretary (Mr. Cocking) then read a paper  
"On Photographic Status" (see page 189), which was followed by a  
desultory conversation, in which the President, Mr Aldridge, and  
others took part.

A vote of thanks having been awarded Mr. Cocking, the  
proceedings terminated.

WEST RIDING OF YORKSHIRE PHOTOGRAPHIC SOCIETY.  

The ordinary monthly meeting of this Society was held on Monday  
evening, the 1st instant, Mr. J. W. GOUGH, President, in the  
chair.

The minutes of the last meeting having been read and confirmed.  

The Secretary laid on the table the February number of the  
Philadelphia Photographer, the photograph which accompanied  
the letter being inspected by the members with interest.

The conversation turning upon Mr. Howarth's stove,  

Mr. Lillingworth stated that since the reading of Mr. Howarth's  
paper he had had one of the stoves placed in his establishment,  
with the performance of which he was highly satisfied, the stove  
heating his gallery, reception room, and work room, keeping  
the former at a temperature of 50 deg., and the two latter at  
60 deg.

Mr. Grunow confirmed the remarks of the last speaker by stating  
that in his gallery, one cold, frosty morning, when he arrived  
had he found the temperature at 28 deg., and in one hour from the  
stove being lighted the thermometer at a distance of five yards  
from the stove registered 50 deg., and in the course of the day  
reached 80 deg.

Mr. Gravells (Halifax) then exhibited to the members the method of developing and transferring carbon prints, developing  
a number possessing great delicacy and beauty, some of them being  
fine examples of lighting and posing.

Mr. Gavins (Halifax) was of opinion that the carbon process  
was not as yet likely to supersede silver printing, as he thought,  
owing to the difficulty in printing, it would require much more  
care than a silver print, which could be inspected during progress.

Mr. Gravells replied that, so far as the difficulty in printing  
was concerned, a man of good judgment in silver work could print equally  
well in carbon. All good printers classified their negatives, and  
nothing more was necessary in Autotype printing. Having ascer-
tained by the spectrometer the requisite number of tints necessary  
to fully print any negative, by marking that number on the nega-
tive there could be no further difficulty, as that was a guide for  
every other print from that negative, one tint being a standard of  
intensity.

In reply to a question by Mr. Braithwaite (Leeds),  

Mr. Gravells said that, in his opinion, an Autotype print  
would bear rough usage than an ordinary print upon albumen-
ized paper; and that, although a certain matt surface was  
insurable from the single tray process, with the method of  
autotype it was easier to use with the operator whether  
he produced a matt or glossed surface. He might produce a print  
with a perfect enamel surface equal to the polished surface of the  
finest plate glass.

In reply to a further question by the same gentleman respecting  
the cost for small pictures,

Mr. Gravells further said that a photographer executing his  
carts in Autotype must raise his prices—he should think about  
twenty-five per cent. If he personally could devote his time to  
printing and developing the prints, he should certainly prefer it  
to silver printing, as it was much more desirable to execute the  
prints in permanent colour; but under the present arrangement  
of business, in which that department had to be left to an assist-
ant, it would probably not be so satisfactory, as the development  
costs were higher than the manufacturing when the paper is  
made and fixed. Therefore, comparing results, a silver print unques-
tionably had the advantage, in being more easy of production.

The Secretary inquired if in practice it was found necessary  
to make allowance for the continued action of the light after the  
time during which the negative had been removed from the  
interest, supposing the prints were to be developed shortly afterwards.

Mr. Gravells said that in his practice he had found it advisable  
to allow a margin if the prints were to be kept for a few hours.

He had purposely been keeping them till next day, with the method of  
autotype he had had his negatives etherized for a week, which  
the action of light, and put away for a short time, it would be found  
to have become insoluble, and if it were developed a tint would  
be found over the whole surface.

The Secretary was of opinion that the question might be solved by printing on tissue from a negative sufficiently dense to  
preserve the whites, placing away for a while, and then develop-
ing. If the action were continued only where the lights had  
acted the whites would remain pure, but if the action were all over  
the film the whites would be proportionately suffused.

On the proposition of the Chairman, seconded by Mr. Rawnsley,  
the thanks of the Society were unanimously accorded to Mr.  
Gravells for his interesting practical lecture.

A paper on the Woodbury Process had been prepared by Mr.  
W. E. Bartho, but as the evening's proceedings would not admit  
of consideration, he had requested to enlarge it and read it at  
the next meeting of the Society.

This concluded the business, and the meeting was then  
adjourned.

Talk in the Studio.

Mr. Morley's catalogue.—We have just received a copy  
of Mr. Morley's recent catalogue of new and second-hand  
apparatus of all kinds—engravings, paintings, prints, and varied  
and extensive array of instruments. Such a catalogue must possess  
great interest for all contemplating fresh purchases.

DALLASTYPE.—Mr. Duncan Dallas has just issued his  
programme of the conditions upon which he is anxious to sell  
the secret of his process to five hundred subscribers at £20 a  
piece. We shall have a few words further on the subject  
shortly.

Photographic prey.—On Tuesday, at Bow Street,  

Charles Urquhart was charged on remand before Mr. Vaughan,  
upon several summonses, for selling and importing pirated  
photographic copies of engravings, the copyright of which  
belongs to Messrs. Graves and Son, the well-known engravers.

In the absence of Mr. Lewis, Mr. Graves, jun., conducted the  
prosecution, and Mr. Silberberg defended. The case had been  
adjourned for the production of evidence to prove the importa-
tion of the photographs, and yesterday several letters to the
prisoner from the well-known firm of photographers in Berlin, Messrs. Seal and Co., were read; and these conclusively proved that the prisoner had been in the habit of importing these photographs for some time past. It also appeared that the prisoner was the agent who obtained the engraving, sent it to Berlin to be photographed, and then sold the copies in England. Mr. Vaughan, in summing up the case, said that he found upon the prisoner, and had examined the defendant's fulls, that the defendant said his object was to prevent the piracy, and not to obtain money. There was also a second charge against the prisoner for selling, and having in his possession for the purposes of sale, a number of indecent photographs. This case was tried by Mr. Justice Ayrton, and the prisoner was committed for trial.

Bath of Acetic Acid before Toning.—The custom prevails largely amongst American printers of immersing the print, before toning, in a bath of one drachm glacial acetic acid in an emulsion removed from Mr. Anthony, clinging to the practice of giving "almost without exception, the American photographers use the fumes of ammonia in their printing. It is a fact that paper thus prepared retains sufficient ammonia to convert the free nitric acid into nitrate, and the paper is coated in a weak solution of acetic—made into acetic of silver. There can be no doubt that the acetic is formed, as it is perfectly visible in the water. We do not know whether the plan of using acetic acid is adopted to any extent in England; but we can assure all who feel disposed to try it that it is a very important appendix to the ammonia fuming process, and almost as useful, from the fact that it saves very long washings before toning, enables one to save all his surplus nitrate, takes less gold in toning, and causes richer tones. Acetic acid can be replaced, and with advantage, by other vegetable or organic acids. Citric and oxalic give especially fine results.

The above assertions are founded on practical experience, as I have used the acid wash ever since I discovered its importance in our everyday work. I hope the photographers of England will not be as long before adopting that acid wash as they have been in the case of ammonia toning."

Collodion-Chloride Prints Turning Yellow.—Mr. H. J. Newton says:—"In reference to the fact that prints on collodion-chloride occasionally turn yellow I will state: A gentleman told me that he had prepared a glass of collodion having his prints turn yellow. I spoke to him about using the acetate of lead for the purpose of eliminating the last traces of hyposulphite of soda. He said he had tried it, but did not succeed until he made a solution of acetate of lead to which a large proportion of alcohol was added, which enabled him to penetrate the film. Since he adopted that plan, he had not had a yellow picture." In our own experience these prints, if fixed and washed with moderate care, never turn yellow except where a sub-stratum of albumen is used.—Ed.

Blackwell Yellow.—These well-known yellow stains can be removed, either from the skin or from brown or black woolen garments, by moistening the spots for a while with per-manganate of potash, and rinsing with water. A brownish stain of manganese remains, which may be removed from clothing with aqueous solution of sulphurous acid. If the spots are old they cannot be entirely removed.—Chemical News

To Correspondents.

* * To AGENTS AND ADVERTISERS.—Next Friday being Good Friday, the Photographic News will be published on Thursday, the 35th. Advertisers should send in their Announcements not later than Wednesday, the 24th.

Mr. Lincoln.—Your negative was distinctly fogged, but just what caused it has the characteristics commonly produced by the use of a new, somewhat thin, and nearly colourless collodion, and a newly mixed iron developer. A little larger proportion of the solution used probably would be permanent. Photographic of Mr. M. W. D. Messrs. Newhall & Co., Boston, probably would be permanent. Photograph of Earl of Kintore. Messrs. Brown & Co., Tampere. Photographer of Sir James Ethington, Bart.

J. T. Rolle.—The Autotype Company, we believe, supplies tissue of the same sort of prints, and we are sure they will be pleasing to the customer. It is probable that, on suitable terms, they could prepare the tissue of any desired colour. The use of permanganate for intensifying negatives made on carbon tissue and transferred to glass film had tried, but we obtained the form was a mixture of manganese. It is manifest that an attempt to tone carbon paper on paper would fail, as the permanganate would be decomposed by the carbon paper, and the ink would be left in the whites. The toning, if it be found to succeed at all, must be effected whilst the image is on the plate or zinc plate on which it is developed before it is transferred to the paper.

Photographs.—You can only remove the nitrate of soda or of ammonia from the silver bath by precipitating the silver and redissolving it.

A. Clarke.—Without a precise description of your operations it is impossible for us to form any idea of the reason why you sometimes obtain a positive effect sometimes nothing. The reasons why the film sometimes slips from your plate may be various, but the most probable reason is the use of a bath containing too much acetic acid. With a bath of acetic acid, especially when there is also some want of skill in manipulating, slipping of the film is not unfrequently a trouble. A preliminary coating of dilute albumen will prove a remedy. As a rule, rain water is not pure enough for the silver bath. Pure distilled water should be used.

J. N. W.—The writer of the article in question resides in Australia, and as such, therefore, there is no possibility that he can express an opinion from his description, that, in the covering of the tent, top and sides are sewed together.

B. B. W.—Your simplest plan will be to describe your qualifications in an advertisement accompanying your paper, stating that you require a certain number of specimen prints which are to be returned.

R. T. Wall.—A negative about half-plate size is a good size for enlargement. Of the lenses you name we should prefer No. 4; No. 3 is also, we believe, a useful lens, but we cannot speak from personal experience. In either case a lens of about eight inches equivalent focus may be used for the work. You will find in our last Year-Book full details as to the preparation of such lenses.

C.—So far as we know, oileographs ought to be moderately permanent; but we have heard of cases in which the brilliancy of the colours has faded. Much will depend on the colours used in printing them. In such matters there is at times a temptation to use cheap fugitive colours, which have a brilliant effect at first, but which do not stand the test of time.

C. H. Homes.—Hypo sulphite of soda may be kept in solution, and will remain good if it have not been used.

C. E. F.—There are two or three modes in which salts of platinum can be used for printing. A paper prepared by mixing gold and exposed to the light under a negative, and then immersed in a bath of chlorides of platinum, will give an image in the latter metal. A process of this kind was described by Dr. Diamond in our last Year-Book. There is good reason to believe that there is much in the permanency of such pictures when carefully produced. But it has not been, as yet, tested fully by time, therefore we cannot say how that may stand after a considerable length of time.

Silver.—The silver solution required for securing an electro deposit of silver on copper is made by dissolving chlorides of silver in a solution of cyanide of potassium. We cannot possibly, however, give you full details on the electro process in this column. Procure a hand-book of electrolyte manipulation, which will cost you about one shilling.

W. A.—Toning may be effected with a solution of absolutely neutral chloride of gold without any addition. On the addition of acetate of soda to ordinary chlorides of gold the acetate of soda is slowly decomposed, the base going to the free hydrochloric acid and monoclinic, whilst a trace of acetic acid is a decided advantage rather than a disadvantage in toning. You should not write questions to the Editor in the letter addressed to the Publisher. It causes delay, inconvenience, and risk of being overlooked.

Mr. Howarth's address is 3, Thornton Road, Bradford.

R. Holgate.—Thanks.

A. W. Adams.—Letter forwarded.

H. Brueers.—Thanks; in our next.

Several Correspondents in our next.

Photographs Registered.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

ABOUT PYROXILIN, SOLUBLE AND INSOLUBLE, AND ITS STABILITY.

The extensive employment of gun-cotton, nowadays, by photographers and surgeons, and especially by miners and military engineers, renders it a matter of absolute necessity that we should be thoroughly acquainted with the properties of so powerful an explosive. It has always been an unfortunate circumstance connected with its investigation, that no sooner have chemists made some sort of progress in their experience of gun-cotton, than a lamentable accident in its manufacture at once puts a stop to— or, at any rate, seriously retards—the further study of its properties in the laboratory. In this country we have had two very serious accidents with gun-cotton: at Messrs. Hall's powder mills at Feverham, very soon after the material was invented, and recently at Stowmarket, an occurrence which will still be fresh in the minds of many of our readers. Other minor mishaps have from time to time occurred, but it is due to the two accidents we have mentioned that suspicions have grown rife in this country concerning pyroxilin. Dr. Vogel's recent remarks upon the subject, which were given in our columns last week, show how much uncertainty still exists in the minds even of chemists about the liability or not of pyroxilin to spontaneous decomposition, and this is not the only point upon which uncertainty still exists. I have no doubt that some kinds of pyroxilin are liable to spontaneous change, but then it is argued that the material in these cases was not properly prepared in the first instance.

When Schoenbein made his discovery first of all, only one kind of pyroxilin was recognised, and it was not till some time afterwards that it was shown there existed two sorts; one perfectly soluble cotton, which all photographers and surgeons make use of in collodion, the other containing more nitrogen, and being far more explosive. This latter, which is termed by chemists tri-nitro-cellulose, is soluble only to a limited degree, for if shaken up in a mixture of ether and alcohol only one-sixth of its bulk, at the most, is dissolved. Indeed, the degree of solubility that tri-nitro-cellulose possesses is one of the tests of its purity; and if, as is very often the case, it is not free from impurities, it is impossible to use it for photographic purposes. It is highly probable, however, that the material used by photographers is free from such impurities, for if more than the proportion of tri-nitro-cellulose stated is dissolved on treatment with the solvent mixture, then the material has not been properly prepared.

Returning, however, to the question of whether collodion gun-cotton and tri-nitro-cellulose are perfectly stable compounds, or whether they are, under some circumstances, liable to spontaneous decomposition or combustion, we approach a point which is hardly so clear as it might be. Professor Abel, the chemist of the War Department, who is one of our greatest authorities on the subject, would, we doubt not, unhesitatingly answer no to the question. If the material is properly manufactured, and the cotton has been thoroughly cleansed of all impurities, to begin with, and is well purified from the acid afterwards, he has over and over again stated his firm confidence in its stability. Other chemists have also expressed their thorough belief in the stability of pyroxilin, and especially of collodion cotton, if manufactured with care and precision; but, here, unfortunately, comes a condition which cannot always be guaranteed. The specimens of gun-cotton which have to our personal knowledge become decomposed, may, of course, have been imperfectly manufactured; but, we would ask, how are we to guarantee a perfectly pure and durable material? The catastrophe at Stowmarket was ascribed, it will be remembered, to the addition, through malice or accident, of acid after the cotton had gone through the conversion process; and this acid, remaining in the cotton when dry, fed, as may easily be imagined, to its ignition. Since that time a very safe precaution has been adopted, which it would be well for all photographers who have a large stock of pyroxilin by them to profit by. It is simply to keep the material wet from first to last, and to store it in this condition. Under these circumstances accidents can never arise, and the drying, which is dangerous if not properly conducted, should be undertaken with small quantities at a time. Any one who has seen a red hot iron bored into a half-pound block of moist gun-cotton, will be at once convinced of the harmless nature of the substance under these conditions, and engineers and miners are now enabled, thanks to the valuable discovery of Mr. E. O. Brown, of Woolwich, to make use of it in this condition, whether for the purpose of mining or blasting. So valuable, indeed, has gun-cotton proved for works of the latter description, that the Arctic Expedition, under Captain Nares, will make use of this explosive for blasting the ice, should the ships unfortunately be unable to free themselves from the masses of ice in any other way. For Arctic work pyroxilin has the great advantage over such blasting agents as dynamite and other nitroglycerine compounds, that when in a frozen condition, it does not become more dangerous to handle; while nitroglycerine, on the other hand, when cœlanged at a low temperature, needs to be employed with extreme care.

The most remarkable discovery which Mr. Brown, whose collarion is well known to us all, at Newcastle some years since, was due, it will be remembered, to the explosion of some nitroglycerine which had become frozen. Keeping gun-cotton wet, besides rendering it at once an innocuous compound, has a tendency, also, to promote its stability; if it be of a suspicious nature, and when conveying it in large quantities from one place to another. In this respect it is worth mentioning that we earnestly recommend the moistening of it first of all. Another plan for reducing the explosive power of photographer's pyroxilin would be for chemists to manufacture it in solid blocks, pressing the short fibre of the gun-cotton, when moist, into little pellets or slabs, as is the case with gun-cotton used for firing, for in this form the material, even when dry, is comparatively harmless and burns fiercely rather than explodes, supposing it is not confined.

We have heard that the Stowmarket Gun-cotton Company have intentions of manufacturing soluble gun-cotton for photographers, this being now almost a waste product at the works, because, as we have just said, a large amount of soluble cotton existing in tri-nitro-cellulose renders the latter unfit for use. As all the guncotton manufactured at Stowmarket is reduced to pulp and then compressed, there is no doubt that the Company would produce their photographic pyroxilin in the form we suggest.

At Faversham, where another guncotton factory exists, calling itself, we believe, the Guncotton Powder Works, the material is also reduced to a fine state of division, for the double purpose of effects its washing more thoroughly, and being able to compress it into any desirable shape. Instead of the cotton being reduced to pulp, however, as is done at Stowmarket, they grind the fibre between millstones, and in this way break up the cellular structure of the cellulose, and prevent it from retaining any trace of acid when finished; for it is the generation of acid fumes that is generally the first step towards the decomposition of guncotton; and any photographer purchasing pyroxilin should always refuse to accept a material of a reddish tint, especially in the event of his not wanting to use the material at once in the manufacture of collodion.

WUNDER'S COLOURING PROCESS.

BY FRITZ HAIG.

Notwithstanding the many favourable opinions which were expressed regarding this process in the photographic

* Photographische Archiv.
journals at the time of its publication, it has never received any extensive application; and the remark of M. Wunder, that after a few years (the process was made known in 1872) all high-class studios would practise the method, has turned out to have been at least premature. There can be no doubt that the process merited more attention than it has, and was given to it, for where the photographer has been placed before the public, they have been well received, and the extra price asked for them has not been grudged.

This fact has caused me to give a little information about the process, and the method of carrying it out, although I cannot say whether M. Wunder still proceeds in the way he used, and which I have here described. From a communication, however, which I have recently received, I may assume that he does not work exactly in the same manner as heretofore, the modifications he makes use of are of but minor consequence.

So far as regards the practice of the process, it is easily carried out. The photograph to be coloured must be toned a little more than is usually the case, so that it may not be of a brownish tint, but rather of a bluish-black colour.

After the photograph has been fixed in the ordinary manner, and washed thoroughly, and dried, it is rendered transparent by the application of a varnish made up according to the undermentioned formula:—

- French oil of turpentine ... 90 grammes
- Mastic, finest quality ... 15 gr
- Venetian turpentine... ... 33 gr

After the picture has been treated with this mixture and dried, it is placed face downwards upon a flat surface, such as a glass plate covered with a sheet of paper, and coloured vigorously on the back with honey or gelatine colours. So as to be able to judge better of the effect of the colouring from time to time as the work is proceeded with, the image is turned over and looked at from the face, upon a basis of white paper. If the picture appears under these circumstances to be sufficiently coloured, it is ready to be mounted. A card mount is coated very evenly with a solution of gum arabic in water. This first coating is allowed to dry, and then a second is applied, and while this is yet moist the coloured photograph is pressed on to it in the ordinary way, and the picture carefully pressed down by means of a soft linen cloth. Perfect adhesion is brought about by gently pressing the photograph down with the cloth. The picture is not put through a rolling-press, but allowed to dry in this condition, the edges of the card being trimmed from gum arabic means of a rag.

Should the colouring show any lack of uniformity afterwards, this may be easily rectified upon the finished picture.

THE PRACTICAL PRINTER IN AMERICA.

XX.

WASHING AND ACIDIFYING PRINTS BEFORE TONING.

It will be seen in the following chapter that Mr. Hearne refers to the practice of immersing prints in acetic acid before toning as a matter of course. The custom obtains almost universally in America, whilst in this country it is comparatively little practised, although it has its origin here.

About fourteen years ago, soon after the use of the alkaline mordant was abandoned in this country, and counterbalanced by the introduction of toned prints, томе.

Mr. Fry, if we remember rightly, introduced the bath of diluted acetic acid previous to toning as a remedy which proved efficient for this trouble.

Mr. Hearne's practical remarks on the action of acetic acid are excellent; but he does not seem quite clear as to the exact action. It is possible that the bleaching operations instead of retarding them, whilst chlorides of sodium would have the opposite action. In toning, it is necessary that chlorides of gold should be decomposed, so as to precipitate the gold on the print. The chlorides of silver and free chloride of sodium resulting from the use of the ordinary salt bath will certainly not facilitate the decomposition of the chloride of gold, whilst acetate of silver by double decomposition, and acetic acid as a reducing agent, will both aid in reducing the gold. Hence the value of the acetic acid bath.

Next in order comes the washing of the prints, although in many galleries the acidifying of them is done first. It is a question whether the prints are the first in the acid water or not, and there are many photographers that believe in washing them first; and then, again, there are many that believe to the contrary. It is not in my mind a matter of so much importance, but for several reasons I am most in favour of washing them first; and so I will commence with the washing.

It was supposed by many photographers, two or three years ago, that the washing of the prints was a matter of considerable time, and consequently they would let their prints wash half an hour in running water, moving them occasionally with the hands. Within the last year or two, however, the photographic printers have found out that such long washing is not only unnecessary, but injurious to the prints; and at the present day, in many of our prints, this part of the process is done in a few minutes. The way we should advise our brother printer to wash his prints is as follows:—Take a half-sheet dish—although any other, if large enough, would do as well—and pour into it lukewarm water, until the dish is about one quarter full. Now place the prints in, by letting a few drop out of your left hand at a time into the dish, while you hold the right, you push them under the water, until you have placed the whole batch of prints in the bath. Again, do this as quickly as possible.

I have recommended to let a few (three or four) drop from the hand at a time in the water, because beginners are apt get some of the prints wet (and let them stay in the hand for some time in that condition before they are placed in the water), if they were to take them from the left hand with the right one, and then place them in the water as they might want. By being very careful, however, they can do it. The objection to getting the prints partly wet and then remaining in that state, even for a few seconds (say eight or ten seconds), before they are wholly submerged in the water, is, that where the water has touched them, they will turn red, and if they are thus saturated by the water after getting out in the dish, they will show spots redder than the other parts of the prints, which will sometimes be very troublesome in the succeeding operations. After the whole batch of prints that are to be toned are placed in this bath of warm water, move them about briskly for about five minutes, and then gently pour the water off into a barrel, leaving the prints to lay flat on the bottom of the dish. Then rinse them with a little more water, and pour this also into the barrel.

These first two waters we save, and throw down the silver in them, by sprinkling a little common salt in the contents of the barrel, upon the addition of which the silver in the solution will be deposited on the bottom in the form of chloride of silver. Upon adding salt to the solution, it will turn blue; whereas, before it was added, the solution was of a cold slaty colour. When this chloride of silver is thoroughly deposited, then draw off the clear water by either a syphon or a faucet, as may suit the taste of the printer.

Before taking for granted that the silver in the solution is all precipitated because you have previously sprinkled salt in the barrel, the solution should again be tested by a pinch or two of salt, and if there is no more precipitate, then the silver is all precipitated, and the liquid can be drawn off without any further delay. When you have rinsed the prints, wash in one or two other changes of water, which you need not save, and then they are ready to be placed in the acidulated water. When the prints are in
The first change of water the washing is done quickly by permitting them to come to the surface, and then gently pushing them down again to the bottom. The prints are washed more thoroughly and quickly in this way than in any other. The time required to do the above washing, after the whole batch of prints are placed in the bath, is only from five to ten minutes.

Now, once this is done, the prints are ready to be placed in the acid water; but, before we do so, we will pause and consider for a few minutes the object of doing this.

It has been supposed by many printers, and in fact that is the general opinion at the present day, that the prints are placed in this bath of slightly acid water for the simple purpose of turning them red, so that they will be able to watch the toning, and also to tone them better. Now this is partly so, but it is by no means the principal object of placing them in the bath, as we will presently endeavour to show.

If our only object in placing the prints in this bath was to make them simply red, why should we not, as was formerly done, place them in a bath of salt water, and thus render that part of the work as simple as the acid does, besides being very much cheaper?

The answer from some of these printers may be that they cannot obtain such nice tones as they could if the prints were 'red up' with acetic acid: and, if that is so, is it not evident that there is something in the action of the acetic acid on the prints that renders them better for the toning process than the action of the salt water?

The action of the salt water on the prints converts the remaining silver left in the prints after washing into the pure chloride of silver; whereas before, part of the silver on the surface of the prints was the chloride, albuminate, and the nitrate, for it must be borne in mind that the salt in the water, when it is floated upon the positive bath, takes up the silver it needs, and forms chloride of silver, which is washed away from the positive board; the nitrate, however, in the albumen of the paper takes up some, and forms albuminate of silver; and, besides this, there is some more absorbed merely mechanically, which is properly the nitrate.

Our attention was first called to the fact we have just explained upon reading, a couple of years or so ago, the action of the positive bath on the albumen paper, when floated upon it, in letters from Mr. D. F. Arnold (Photogr. News, September 1870).

Thus you see that all of the silver that was on the surface in different forms is now reduced to the same form, viz., pure chloride of silver.

Now if you were to place the prints in a very diluted bath of acetic acid instead of salt, then the remaining silver in them will be perfectly converted into the acetate of silver, if they are permitted to remain in the bath long enough for the acid to overcome the other natures of the silver, and that is why I have below recommended the prints to remain in the acid water ten minutes, for the acid to do its work; and that is also the reason why (if the prints stick together for any length of time), even if they have once been wet all over with the acid water, the prints at those parts where they had laid close together will not be properly converted into the acetate of silver, and will not tone well, although they may not have changed colour any — i.e., those parts of the prints which may be stuck together will be full as red as the rest of the prints, and thus to a careless eye may be all right; but in the toning of them, the printer will perhaps wonder what makes some of them tone so much better than others, although in the distribution of colour on the surface they seem to be all alike.

The acetate of silver is worked upon better by the toning solution than either the chloride of silver or the mixture that composed the silver on the prints before they were placed in the acid or salt water (being chloride, albuminate, and nitrate).

* It must be borne in mind that the paper having been toned, there may not be any difference in form of acetate of silver, as would be the case if only free nitrate were present in the prints.—Ed. Photogr. News.

The proof of the above can be observed by the toner as he tones the prints that have been 'red up' in either the salt or acid water; and then again as he tones those which have not been 'red up' at all, but simply washed.

I do not mean to give the young beginner the impression, however, that prints that have been placed in the salt water, in lieu of the acid water, will tone badly in the toning bath. On the contrary, they will tone very fairly. The good old-fashioned tone (good if it is old) will show; but I do mean to say that better tones can be obtained with the use of the acid water, provided the conditions are right. An excellent toner may take prints that have been placed in salt water, and obtain better results than an indifferent toner would with prints that have been placed in acid water.

The quantity of the acetic acid required is just sufficient to properly convert the remaining silver in the prints into acetate of silver, as has been said before, and no more. I use generally about an ounce of the acid to the gallon of lukewarm water. I use lukewarm water because it will more quickly do the work required than cold water.

In Germany and England glacial acetic acid is used; but when that is used I say, if not equal to the good old-fashioned toner, as it is much stronger than the acetic acid No. 8. This acid (glacial acetic) is not used at all, I think, in this country, and when the acetic No. 8 can be obtained it had better be used, as the glacial is very expensive, more so than it is proportionally stronger.

When you commence to make your acid bath, place the lukewarm water first, and then float the salt out of the bath, and then after measuring out the quantity of the acid in a small vial, pour it into the water at different places, and then, with your hand, stir the water well for about one minute, so as to get the acid thoroughly mixed with the water. Now place the prints into this bath as quickly as possible, in the manner described in the preceding chapter, i.e., by permitting two or three to fall at a time from the left hand, while with the right hand, I repeat, as quickly as possible.

When you have placed every print in the acid water, then keep them in constant motion for ten minutes, for the reason above mentioned (viz., that the silver in the paper will be equally converted into the acetate of silver), and then pour off the acid water and save it (for this acid water has released still more silver from the prints), and then place the prints in the toning bath (see the Proceeding of Photographers), so as to remove the bad smell of acetic acid from them. It is very necessary that the prints be washed well after acidifying them, because, if the superfused acid water is not well washed from them, false, deceiving tones will be obtained in the toning bath, which will in a great measure be destroyed in the further operations with the prints. The tone will be a superficial and uneven one. The prints are finally sufficiently washed for the toning operations when, upon smelling them, there is only a very slight vapore of the acetic acid given forth.

ART-CRITICISM.

BY W. NEILSON.

Retouching.—By "retouching," I mean painting lights on the negative, or "bumping" up. It almost seems pre-assumption to speak against it; for no fashion has been more prevalent or more generally admired since the graceful crinoline went out of date. It has even been exalted into the "artistic touch" which gives brilliance to a photograph; reminding one somewhat of the artistic touch a girl gives her cheek when she dresses in the highest height of fashion, and becomes brilliantly vulgarised. It is but common humanity to sympathize with the next generation when they shall see the general run of the brilliant "retouches" of their fathers looking as if the originals had been touched with leprosy. It is altogether a mistake.

* Concluded from page 124.
Art is not to be juggled with. Trick and tinseling of every kind is alien to its nature. Every art is complete in itself; indebted to itself alone. What would you say of the painter who could not finish his picture without calling in extraneous aid, wholly apart from brush and pigment? You would say either that painting is an incomplete art—that is, no art at all—or that the painter was incompetent. In like dilemma, the photographer who resorts to the brush casts a slur either on himself or photography. Either the one is not a true art, or the other is not a true artist. Perhaps it may be said that certainly is true; yet retouching bears the same name. To retouch is the words of the "I am Done," when George IV., who had come to believe that he led the charge at Waterloo, appealed at a dinner party to the Duke of Wellington if that were not the case, the Duke replied, "I have heard your Majesty say so before."

Photography, like every other art, must act solely by its own law, having its own idiocy or peculiar constitution, according to which it can render any desirable requirement of light and shade. It is difficult, no doubt; but difficulty is the boast of art and test of the artist. Photography should not imitate the effects of painting or chalk drawing. To imitate is to confess want of originality—the resource of incompetence. Photography, as different from other modes of representation, should be true to itself, and not only, as commonly, accomplish by its own idea the subdued tone of graduated lights and shades, in which alone its charm consists. It should work, so to speak, in a minor key. If a painting may be compared to the effects of a sunlit view, photography may rather be compared to the effects of a moonlit view. Take away from it this difference from other modes of representation, its subdued rendering, and you leave—what? Brilliancy, what is translated into the vulgar language, means "chalkiness."

I object, then, to retouching:—1. Because by imitating the high lights of painting it depraves from the idiocy of photography. 2. Because introducing a high light destroys the subdued effect of the graduated scale of shades peculiar to photography. 3. Because it destroys the texture, always proportionate to a less of a chalky or flat effect. 4. Because it interferes with the likeness. If we could have a photograph of Shakespeare, would you wish it to be retouched. No. And why? Just because it would interfere with the likeness. Every man should be represented as he is, and not what the retoucher thinks he should be; unless the man, aspiring to the beau ideal, is content to be turned out as an ideal bean.

But if you have, as I have, attended at the first photographic exhibition of his day. If ever photographer stood on the higher platform he is the man. Latterly Rejlander never retouched.

These remarks are, of course, not intended to bear upon professional photographers, may of whom, I know, have to do what they dislike in order to please their customers. Trade, as well as art, has its prerogative—"Who live to please must not live to live." But amateurs, at least, are freemen. We know that there are men among them of taste as well as skill; and it is for them especially—if they can forego the easy pecuniary that is acquired by a few dabs of the brush—to rely upon their art, and show the subdued style of beauty peculiar to photography, without which it has no pretense to be called an art. Already there are prophetic signs. I am told that in Germany a reaction is taking place, and that retouching is beginning to be regarded as a mere "dodge," unworthy of any man who has the capabilities of an artist.

Life-size heads.—Mr. Crawshay has rendered great service in calling attention to the capabilities of the lens. Not having seen the pictures which gained his prizes, I can merely say that I believe the judges were conscientious in their verdict, and that the pictures were excellent, even without allowance for the attractions of the fashionable brush. That life-sized heads should be confined to the portrait painter I think can be proved by the fundamental principle of art. But, passing that, there are two difficulties in taking direct life size heads. The one is that few skins can stand the near scrutiny of the lens without losing on the negative many uneasily spots. Skins that show no frown is to the eye often do so to the lens. The other difficulty lies in the point of the nose. This very prominent feature is very apt to have, whether it is curled downwards or upwards, a prolongation at the point, as if nature intended humanity to be led by the nose, which it very often is. In most positions of the head this nasal knob perks itself unduly into the light, which, falling at an incorrect angle, becomes more perceptible, and an amount of glare that causes exaggeration in the negative. For the same reason, though the hand be in perfect focus, the glaring fingers come out enlarged. This happens in small photographs also. Of course there will be distortion if the focus of the lens be too short for the occasion.

As somewhat in illustration I have laid before you three of the pictures I sent to the exhibition. These were not retouched and the fact is that the photographic novel. of course, look flat and dull beside those made brilliant with the "artistic touch." Since the exhibition the print of the large head has had the spots on cheek and forehead touched, giving it a more finished look. Several artists have seen it, and found the drawing correct, save a slight width at the nasal knob. They also agreed that it has a richness of effect not found in the larges and a more striking likeness. I think there is none who has all this and could be improved by heightening the lights. The reply was, No! Indeed every artist I have talked with speaks of retouching with abhorrence.

In expressing opinions in a paper of this kind one is apt to appear dogmatize. If I have done so it is partly owing to the fact that any artist I have had an opportunity of conversing with on the subject have substantially agreed with what has been advanced.

In concluding, I am aware an opponent might say, "You have, for the most part, merely expressed opinions without meeting objections which might be brought against them. My reply would be, "I grant it, sir. One can't do everything in half-an-hour. I have merely tried to shoot you on my line; and if it do you no harm to remove from that point of view, and indulge in a little contemplation without partiality, and, if possible, without prejudice."

THE ART OF POPULAR ILLUSTRATION.

By Henry Blackburn.

Would it, then, be too much to ask of those who cater for and really create the public taste, that they should give us one of two things, or rather two things, in our illustrated newspapers, the real and the ideal? *

* Continued from page 187.
1. Pictorial records of events in the simplest and trustiest manner possible.

2. Pictures of the very highest class that can be produced on wood, and printed with the type.

If I were pressed for examples of excellence in each division as issuing from the press to-day, it would be difficult, and might seem invidious, to select them. Mr. Samuel Smillie of London, Nares, making a sketch on a cigarette paper as he walks may be more truly conceived as one of the genius d'artiste, ready to smoke or to swallow it on an emergency, is a good picture of artistic activity in this direction; but speaking generally, I would say that, in the first division—in fact, the true—some of the best sketches from the seat of war have appeared in the Illustrated London News, as in the Monde Illustre, published in Paris. They do not fail all the conditions asked for, and even they sometimes lack the simplicity and decision of touch which we hope to attain by training.

In the second division, "the ideal," the public need not be reminded that the Graphic newspaper is producing work of a higher artistic order than anything we have been accustomed to in newspapers. The illustrations by Sir James Lonsdale, Lord Houghton, H. Allingham, and others, which have appeared lately, are superb productions of fine drawing and engraving, in composition, colour, and in all technical qualities, the highest standard of excellence yet achieved. In this branch of illustration there is legitimate scope for both artist and engraver; but it is a question of taste how far events of the day should be treated in this way. Unfortunately, such, for instance, as the accident on the Matterhorn, depicted by Dore, and the burning of the Cospicua, by Durand. Some will think that such scenes should be left to the historian, he be painter or man of letters. In illustrations to novels and tales in newspapers and magazines, there is often more thought given to producing a work of art than to illustrating the text. The result is generally satisfactory to the public, but it is scarcely illustrative in the true sense of the word. Portraits, although they have been well described as the "ideal biography of the man," belong to the first division, the real, and in no branch of illustration do our newspapers more legitimately excel. The portraits of Dr. Manning, and of Carlyle, which have appeared lately, are remarkable examples of what may be accomplished, both in illustration and engraving on wood, for the weekly press.

Here, then, are two opposite schools of illustration which only require to be kept distinct, each in its own place, and our interest in them would be doubled. We ask first for a record of news, and then for a picture-gallery, and to know, to use a common phrase, "which is which." In the illustration of books, I would remark generally that the present fashion of drawing and engraving is too elaborate, the cost of which discourages publishers, and deprivates the public often of what it would care to see. Instances of this occur every day. I saw lately the author of a book of travel and exploration lay before his publisher a collection of sketches, photographs, and the like, which he had taken years to collect. To have seen these, or any other, presented in the true manner, in his book, would have been a valuable addition to our stores of knowledge. But the publisher was wise, from a business point of view, and out of some fifty of the most important subjects he selected ten, and had them drawn and engraved in the best drawing-room manner. The book is a success financially, and everybody is satisfied excepting the author himself, who knows that perhaps half the interest of that book lies in a drawer in his own chamber—waiting for the millennium!

Next, as to the processes for reproducing drawings, especially those adapted for the fac-simile reproduction of sketches. During the past few years so many processes have been put forward for producing drawings in relief, for printing with the type, that it has become a business in itself to test and understand them. First, as to wood engraving. I need not tell the practical part of my audience that on the 10th of March, 1875, the best known process is wood engraving; at least, it is the best for fac-simile reproduction of drawings, as at present understood in England, whether they be made direct upon the wood or transmitted by photography. There is no process in relief which has the same certainty, which gives the same colour and brightness, and by which gradation of tints is so completely possible, as which we ever will know, how much the engraver has done for the artist. "For good or for evil," it may be said; but I am thinking now only of the good—of occasions when the engraver has to interpret the artist's meaning, and sometimes, it must be confessed, to come to the rescue and perfect imperfect work. The artist who draws for reproduction by chemical and mechanical means is at least his own resources. He cannot say to the acid, "Make these lines a little sharper," or to the sun's rays, "Give a little more light;" and so, as we cannot always have good wood engraving, as it is not always cheap enough or rapid enough for our needs, we endeavor to draw in positive black lines exactly what we want reproduced, either a sketch in line or a diagram, or a more finished drawing, with tints obtained either by engraving, or by some other process, and resort to one of the photographic processes by which a stereo block can be produced, if necessary, in six or eight hours.

A wonderful and startling invention is here, worthy of a land of enchantment, which, without labour, with little more than a wave of the hand, transfixes the written thought, and turns it into a monument; by which the most delicate and dainty stroke of the pen is not only rendered visible for the eye to decipher, but it is brought out in sharp relief, as bold and strong as if hewn out of a rock. Here is an argument for doing "the best and truest work we can," a process that renders indestructible—so indestructible that nothing short of cremation would get rid of it—every line that we put upon paper: an argument for the new, for the fine, for the mechanical and the artistic, that is the method best adapted for photographic reproduction by the press. As to the relative value of the different photographic relief processes, that must be decided by experts. Speaking generally, I may say that there are six or seven now in use, each of which is, I am informed, the best, and several of which I know to be applicable to cylinder machines in the same manner as a metal cast from wood engraving, and improvements in these methods render us working more and more rapidly that what was best yesterday will not be the best to-morrow; and it is a subject of such importance that it might be worth while to devote a special evening to its consideration.

In answer to the question—perhaps on many lips to-night—"Has anything worthy of the name of an artistic result been produced by these relief processes?" I answer emphatically, "Yes," and that the results obtainable are, as yet, only half revealed. Drawings reproduced in relief by photographic processes differ curiously from each other, and all, of course, differ widely from wood engraving, which is never in absolute fac-simile. As adjuncts to, but not as substitutes for, wood engraving, the processes have great value, both in the printed page and in the sheer technical value, sometimes a quality of work which, for technical reasons, cannot be accomplished by the graver—a quality for which there is no other word than artistic. Some of the blocks are deficient in relief, and in the bearing up of the fine lines; but some have answered admirably, and have had as many as 100,000 impressions printed from them. The specimens put forward by the promoters of the photo-relief processes are very unequal; some are very good, and some, I must admit, are very bad indeed. They say, "Give us good work, and we can reproduce it;" but they want something more than this; they want drawings that will be reproduced mechanically; they want something, in fact, which, for want of practice, few artists are able to give.

(To be continued.)

THE ALBUMEN-BEER PROCESS.

The testimony borne by Captain Abney to the simplicity of the Albumen-beer Process, and the sensitiveness and trustworthiness of the plates under circumstances of special importance, must invest the subject with unusual interest to all dry-plate workers. We have already published copious details of the process, and we give to-day the resume of the operations used in the Transit plates. To the flaxen standards thus laid before the photographers, we are enabled to add a few further hints of value, obtained from Captain Abney in response to questions which arose to our mind after hearing his paper and examining the very fine quality of the negatives the process presents.

First, as regards the albumen. In Captain Abney's experience, dried albumen answered in every respect as perfectly as albumen from fresh eggs; and in view of the excellent results thus obtained, and from the advantages afforded by this preparation, he expressed a conviction that it might with advantage supersede fresh eggs in the majority of photographic applications. The primary difficulty standing in the way of this arises from the fact that samples of dried albumen vary, some being perfectly soluble, whilst other dissolve less freely, and leave some insoluble residue, a fact which at once introduces uncertainty into the strength of the solution. Captain Abney, in his paper of Egyptian experiences read before the Society, refers to a sample from one maker as always dissolving perfectly. This sample, we ascertain in the interests of our readers, is prepared by Mr. Thomas, of Pall Mall. It dissolves perfectly in cold water in a few minutes, fifty grains of it in one ounce of water furnishing, in Captain Abney's experience, a solution equivalent in all respects to the white of a fresh egg. According to the instructions of the maker, if we remember rightly, seventy-five grains per ounce should be used to produce a solution equivalent to white of egg; but Captain Abney never found it necessary to use more than fifty grains.

One of the most frequent enquiries which has reached us as regards this process has had reference to the quality of the ale used. Captain Abney's answer to this question is: "Any ale, so far as I know. I have used many kinds with good results, but we use, by preference, Tennent's ale." A good pale ale, moderately rich in malt and hops, is always found to answer well. An important point, however, requires attention. When it is least fit for drinking—that is, when it is quite flat—it is best suited for use in photography. Captain Abney found it necessary, with boiled ale especially, and with draft ale if it were at all brisk, to allow it to stand some hours in an open vessel, sometimes heating gently, in order that all the carbonic acid should escape, otherwise this, when brought into contact with the ammonia, would form carbonate of ammonia. Another point in connection with the ale it is important to observe: it should never be mixed with albumen solution until immediately before use, and any remaining over should be thrown away, as its use would only issue in uncertainty and probable failure. The reason is simple: if the solutions are suffered to stand for a time after being mixed, a precipitate is formed by the reaction between the tannin in the ale and the albumen, and two elements in the success of the process, tannin and albumen, are, to a certain extent, eliminated from the preservative.

At the mode of modifying the physical condition of the collodion by the addition of water, described by Captain Abney, is important. The method is a very old one, but it has not received sufficient attention. In most dry processes it is of great value, and also frequently in the wet process. A dozen years or more ago Mr. Window described in the Photographic News a dry process without preservative, yielding very sensitive and certain plates. An important element in the success of the process consisted in adding water to the collodion to the utmost point possible, without rendering the collodion glutinous and its film reticulated. Many persons tried the process and failed, and in every case where we could trace the operations we found that the process of watering the collodion had been neglected as unimportant and trouble some in working later plates by the wet process, especially in hot weather, this treatment of the collodion is most valuable. When, owing to the hornly repellent character of the film, must silver stains are troublesome, watering the collodion judiciously is an almost certain cure. The procedure is one, however, which requires care and judgment. The best plan is to take a portion of the collodion to be treated in a large dish, weighing the rate of two or three drops to such ounce at a time, shaking well, and then, after allowing the bottle to stand for a time, trying a plate. When the extreme verge has been reached, and crispness begins to be apparent, a little of the unwatered sample may be added to restore working conditions and get rid of crispness. There are two different defects produced by too much water not always present to each other. The most common is the production of a reticulated, crude film. This is easily removed by adding a little untrebled collodion. The other defect is an irregular glutinous consistency, giving an irregular, lumpy film. This is not always got rid of at once on adding more untrebled collodion. When once it is produced, it sometimes happens that the addition of much collodion is necessary, and in conjunction with the fresh collodion, will effect a cure.

In the albumen-beer process, Captain Abney finds the watered collodion invaluable. It will readily be seen that such collodion should be valuable in all dry processes. The film prepared with such collodion is much more permeable by water than a film from unsophisticated collodion, and, consequently, much more readily permits the removal of free nitrate of silver by washing. It also permits the ready penetration of the preservative and sensitizer—a condition manifestly of value; and it receives, and absorbs the aqueous solutions used in developing easily, so making the process of development almost rapid and easy as that of a wet plate.

ENAMELLED OR "GLACE" PHOTOGRAPHS.

The enamelled surface for portraits appears to be the rage amongst American photographers at present. A substitute is proposed in the Photographic Times in the use of what is termed "diamond glossy" paper and colloidio-chloride of silver. The paper in question appears to be the same as the ordinary glazed on which the deposit of a pigment and a glazing process. We have frequently used it for colloidio-chloride printing with great advantage. It gives a fine surface and great delicacy in rendering every detail in the negative.

The following method, given in the same journal as the
mode employed in Frederick's studio (one of the first portrait establishments in New York), may afford good hints to those who have not yet succeeded in producing enamelled surfaces satisfactorily.

"Have your glass free from bubbles and scratches—plate glass, size about 54 by 73 inches for cabinets. Clean well, and run a little streak of gum around the edges. This precaution must be taken, or else the picture will leave the glass before it should do so. When the gum is dry, it is ready for the collodion.

Coal-tar, ether, alcohol, glycerine, cotton. Coat the plate with this, and set away to dry: half an hour will be enough.

**Gelatine No. 1.**—Best French gelatine ... 1 ounce Water ... ... 12 ounces

Let the gelatine soak in the water twelve hours, then heat either by sand-bath or glue-pot principle; never let the heat be over 180° Fahrenheit or under 115°. Place in the solution, one by one, the pictures which you wish to enamel. Take your collodionized glass and warm it slightly on the back; then take a picture from the gelatine solution and lay it carefully on the glass, face down; rub the back lightly with a piece of cotton flannel, in order to remove the surplus gelatine on the glass and picture. Let the surplus thus removed run into a suitably prepared drain, lay the glass down flat, and keep on until all the pictures are thus placed, and let them remain half an hour; they are then ready for the next process.

**Gelatine No. 2.**—Gelatine same quality ... 2 ounces Water ... ... 8 "

Soak in this solution the cardboards for backing from five minutes upwards, and mount on back of pictures, in the same manner that pictures were placed. These mounts should be thin enough to allow of two thicknesses being placed; then put the glass aside for twenty-four hours or more in a dry place; the longer they remain up to a certain time the finer the glass; they are then ready for cutting; in doing which, be sure to cut inside of the gum which is placed on the edge of the glass for holding down the picture. Be sure not to allow the gelatine to get over-heated, as this destroys the whole process. Also be sure to slightly warm the glass before placing the picture on it, in order to drive off the dampness. Don't heat too much, as this will injure the collodion film.

"The collodion may be varied according to atmosphere; if a dry atmosphere, use more alcohol, and less cotton. The finer the surface of your first backing-board which comes in contact with the picture, the finer the result. The gelatine must be thin enough to allow of two thicknesses being placed; then allowed to cool, then re-heated before using. The process of staining or filtering produces small bubbles, which only disappear by cooling the solution. Never strain or filter it unless actually necessary to get out specks or dirt. The small card pictures need only one thickness of cardboard for backing."

**SOFTNESS AND INTENSITY.**

The *Western Photographic News* (Chicago) gives the following summary of the conditions which produce intensity and contrast in negatives:

"The normal conditions that produce contrast, chemically are, first, an increase of the per cent. of acid in any of the solutions; second, tincture of iodine in the emulsion, which may be classed as an acid, as it produces a vigorous acid in the bath; third, short exposure is a well-known method; fourth, certain positions of the model, and directions of the light and camera during exposure; fifth, motion of the plate during development; sixth, short setting of the collodion film; seventh, short immersion of plates in bath; eighth, certain conditions, such as washing and development. This has been relied on too much, as it is one of the lesser causes of this effect, and then only conditionally true. Some of the abnormal conditions of excessive contrast are, first, impure chemicals, and an inharmonious adaptation of the solutions to each other; too new a cadmium collodion; too alkaline a bath, or a nearly neutral one. A neutral bath, if impure, gives great contrast, and hazy or foggy effects; acid here will give softness, if used in proper proportion, and merely to neutralize or slightly acidify. If a slightly acid condition does not remedy the fault, the bath should be purified by neutralizing, and subjected to the permanganate of potash and light treatment, or light simply, as preferred. The causes that operate in an opposite direction, to produce softness, are given inferentially the ill-suggested, in each case of excessive contrast. I will briefly enumerate a few.

"First—decrease the proportion of acid in one or all of the solutions. Second—Long exposure. Third—Certain positions of the subject, and direction of light upon the same. Fourth—A quiet plate during development. Fifth—A copious use of developer, which produces softness by washing the silver off the plate. Sixth—Long setting of the collodion film, and long immersion in the bath. Seventh—An increase of the per cent. of iron in the developer. Eighth—Alcohol in the developer, which gives softness as well as lowering properties."

---

**LOOK OUT FOR YOUR EYES.**

BY H. BRUTER.

Attention is again being called to the sanitary condition of the operating room, and, despite the reiterated warnings against the use of cyanide, its convenience, safety (as regards the stability of negative), and quickness of result, will never banish its employment whilst hypo is the only substitute. Ether and alcohol have both had their share of abuse—none more than chloroform; the ill-springing from focussing by the eyes seem totally to have escaped general criticism. Perhaps the following argument may direct more attention to this neglected portion of human economy.

The easy focus of the eye is from nine to eleven inches, varying according to physique, on the same principle that, although we are all generally formed alike, particularities make one tall, another short; one stout, others thin. This will also apply to the slightly varying focus of the eyes, which, for the sake of distinction, will be called the "normal focus."

If a piece of printed matter be placed at this distance (normal focus) from the eyes, and both eye and hand instinctively hit the distance, the eyes feel easy, unrested, and direct the subject to the point; the eye should be able to focus at the right point, still the sight is easy. Direct the gaze to the distant stars, no unnatural effort seems to arise in their viewing. Try the converse; at the distance of normal sight place the printed matter; then gradually advance it towards the nose: every inch of advance increases the feeling of uncomfortable, till the nerves are absolutely palpable in their tension, and quite a feeling of relief ensues when the sight returns to its normal point. This experiment is adduced to show that nature has given illimitable sight beyond the "normal focus," but the power of seeing within this focus rapidly diminishes.

The photographer is placed in the latter condition who, to distinctly view the camera image, has to place his eyes far within this normal point, and, by a curious anomaly, has to ignore the laws concerning his own sight to conform to others governing the distinct vision of small bodies. Although the eyes in the end adapt themselves to this new order of vision, still the penalty must be paid in impaired vision, in seeking to force an unnatural power on the eyes, viz., making them a microscope; and the image on the ground glass when the entire depth of the subject is represented a carte portrait may truly come under that denomination.

Two circumstances prevent the immediate perception of this accuring evil. Firstly, during the bloom of early life
the physical power is sufficient to mask the harm, acting in the same manner respecting any other bodily excess. Secondly, the defect, though daily happening, is so inconsiderable as to be unperceivable, and is only felt when declining years, and that peculiar decadence of the eye (arcus senilis) weakens its organization, when the deterioration of the eye is found to be in greater proportion than years or the change alluded to would warrant.

I am afraid this will appear to you more than thought distant, "use a focuser." The usage and adjustment of this well-known instrument would be a platitude to describe, and the practice of a large and rapid business, extending over a lengthened period, gives an emboldenment to the above advice. Without wishing to make an invidious selection, the form of eye-piece manufactured by Solomon, of Red Lion Square, is as good and as economical as any in the market; but where all these instruments must be insisted upon: the absolute necessity for a "clamping ring," for without it the constant pressure of the eyebrow will little by little derange the focus, and blame might be attached to the performance of the instrument, due only to the neglected precautionary measures of the operator.

FRENCH CORRESPONDENCE.

AIME GIRARD'S MICROSCOPIC INVESTIGATION OF PAPER FIBRES—BORIC ACID IN THE DIPPING BATH—TONING WITH ACETATE OF LEAD—THE FRENCH TRANSIT OF VENUS OBSERVERS—PHOTOGRAPHIC EXHIBITIONS.

M. Aimé Girard, who has communicated to the Academy of Sciences the results of some interesting investigations which will be of some importance to photographers. For more than twenty-five years complaints have been made, and not without cause, against many paper manufacturers, concerning the material produced at their factories, the quality of paper made by the best firms being sometimes called into question. The reasons of these complaints have been sought for far and wide, and all kinds of means have been resorted to secure an improved product by modifying the raw material employed in the process of manufacture. M. Aimé Girard has now taken up the question from a new point of view, making a microscopic study of the vegetable fibre of which the pulp consists, and in this way he has been enabled to determine the precise condition in which a vegetable fibre should fulfill in order to produce a paper of first-class quality. The fibre must be long and thin, and should be capable of being doubled back upon itself with ease, so that the paper may acquire solidity in the process of felting. The tenacity of the fibre, upon which it is usual to lay such great stress, is only of secondary importance, it appears, for when a sheet of paper is torn, the fibres are not entirely torn, but glide between one another. The result of his experiments has led M. Girard to divide into five classes the different materials which serve for the fabrication of paper, and these he thus defines:—1. Round and nervous fibres. In this class there is to be found the fibres of flax and hemp only. 2. Round and smooth fibres slightly nervous, such as the esparto grass, the agave, and the agave cane. 3. Flattened, or ribbon-like fibres. In this class there is only one material to be found: the pulp produced from wheat and rye straw. 4. Flat fibres, like those of cotton, or such as are extracted from the wood of the mulberry tree and bamboo by chemical means. 5. Imperfect raw material. This is obtained from wood by mechanical means, and does not consist of fibrous matter all, but of bundles of fibres adhering to other fibrous matter in some other way. They are suitable only for coarse paper, which only requires a little beating.

Such material as this introduced into pulp can only serve to produce a very imperfect paper. In the course of his investigation M. Girard was not content to examine the different fibres under the microscope of which he speaks, but he photographed them and prepared enlarged pictures from the clichés, so as to be able to study their form more deeply, and to classify the types.

At the last meeting of the French Photographic Society M. Fleury Hermagis alluded to the employment of boric acid for acidulating negative baths. No handbook of photography has yet advocated the employment of this acid for the purpose indicated; nevertheless, according to our skillful optician, it may be so employed with advantage, always keeping the bath slightly acid with it. "It is a known fact," says M. Hermagis, "that the addition of small means of nitric acid the best collodion is exposed to partial lifting of the film, and the latter, moreover, loses some of its sensitiveness. It is well known, also, that acetic acid, less energetic in its action, evaporates very fast, so that fogging and other defects, which are dissipated by its presence, reappear again just at the most inopportune moment. Boric acid has the triple advantage of not causing at all damages to the coating at once, and also of causing the film to lift, and of preserving the sensitiveness of the iodobromide of silver in the same degree as if the dipping bath was in a neutral condition. The operator commences by putting his bath into a neutral state by the use of a concentrated aqueous solution of bicarbonate of soda. A few drops added to every hundred grammes of bath will suffice. As soon as the bath is in a state of equilibrium, enough soda has been added. The bath is then filtered, and acidiolated with about two or three grammes of boric acid for every litre of solution. A white colloidal will work very well under these conditions." M. Hermagis states that with a bath of this kind the time of exposure may be reduced by one-sixth. It is essential that the boric acid should be added to the bath, as it does not answer with this treatment. It is necessary also to take great care not to change the iodiser in the collodion, but to have a special bath for every different kind of collodion. M. Fleury Hermagis adds that you may succeed sometimes without fulfilling these conditions, but they are, nevertheless, necessary for operating smoothly and uniformly.

The skillful provincial photographer has addressed to me some interesting observations upon the employment of a fixing agent containing acetate of lead. The process, which was published in England twelve or thirteen years ago, is scarcely ever employed in this country, although it would be well, perhaps, to make use of it. The correspondent of whom I speak has still in his possession prints made by this method, which, in ten years, are not much different in this way. Despite their age, they have preserved all their brilliancy in the whites, and this freshness they possessed from the first, while other pictures, produced on the same date, toned and fixed in the ordinary manner, have faded very perceptibly, M. Aleide, my correspondent, deduces from this that acetate of lead, far from injuring the prints, on the contrary, has protected them. A picture may remain more than thirty minutes in a bath of hyposulphite of soda containing acetate of lead and ten per cent. of bicarbonate of soda, without the whites being in any way altered. The old prints of which he speaks were only passed into an old acetate of soda gold bath, which had been exhausted, and then, without being washed, put into the hyposulphite solution, prepared as we have described. They were there immersed for forty-five minutes, until they had assumed a beautiful violet tone, which they still preserve. The whites have remained quite pure, and the albumenized paper retains to this day all its brilliancy. In this process the washing requires much more care, and it is necessary that the water should be renewed from time to time. If a print is not rapidly washed, it assumes a yellowish tinge, which defaces the color. Last Monday M. Mouches, one of the French savans who were instructed by the French Academy to observe the Transit of Venus, gave a personal account before the members of the difficulties he encountered, and of the dangers he had to undergo, before he attained the success that fell to his lot. He had passed three months on St. Paul's Island, and I need not say that he had a most enthusiastic reception by the Academy. M. Mouches has
described in detail all the work that his companions and himself accomplished during the duration of the transit. By a circumstance as happy as it was unexpected, the weather, which had not ceased to be very unfavourable, cleared up suddenly at the right moment, and during the whole time of the transit it was possible to secure photographic images of the phenomenon. As many as four hundred and forty-three Daguerreotype plates were secured, and one hundred and forty-two collodion clicks, from which, however, must be deducted sixty-seven Daguerreotype plates and two hundred clicks to be very unsuccessful. There remain also four hundred and eighty-nine good results, which may be employed for making micrometric measurements, which will be at once conducted under the personal superintendence of M. Fizeau. When we take into consideration these prodigious results, we cannot but congratulate ourselves on the marvellous progress that has been made in photography during the last few years.

At the Palais des Champs Elysées they are organizing at the present moment an International Exhibition of industrial products for exportation, and a place will be reserved for photographs and photographic apparatus. An old photographer, M. Moulin, has charge of this portion of the exhibition, and he has just addressed to his colleagues an interesting letter. Another exhibit of a purely photographic nature, is also about to be organised at Brussels, as your readers have no doubt been informed, and it is in this direction that the attention of our artists is turned for the present. The Parisian photographers will, most probably, avail themselves in good numbers of the hospitality of the Belgian Photographic Association. It is very desirable that our English colleagues should also take part in this exhibition, so that the assembly may gain in interest and importance.

ERNEST LACAN.

PHOTOGRAPHIC OPERATIONS IN EGYPT IN CONNECTION WITH THE LATE TRANSIT OF VENUS.

BY CAPTAIN ABNEY.*

I have been asked to give an account of my photographic operations during my late visit to Egypt in connection with the transit of Venus. This I am happy to do. I should like to add, in some degree, to the interest of that remarkable country—remarkable for its climate, its river, its ruins, and its history. Where my chief work lay was at Aswan, on the south of the 60th degree of latitude, and it was a matter of no small anxiety to me how I should transport all my instruments and observatory to that spot. The boats, or "dahabees" as they are called, would hardly have taken all unless I had engaged one which was out of all proportion to the passenger accommodation which I required. My party consisted of myself and three Sappers, whose names I should like to record, as owing to them, in a great measure, resulted the success of my work. They were Sapper Laffeaty, chief photographer, and Corporal Milne and Sapper Farr as assistants. I may here say that the hearty good-will with which they worked and carried out instructions, sometimes preparing plates to the small hours of the morning, is beyond all praise. I may truly say that all failures (for failures at first there were not taken to heart by them, equally as much as by myself; and had not it been for the *enfente cordiale that existed between us all, the photographs we brought home might not have been so good even as they are. Honestly, I never knew so thoroughly before what a godsend it is to have soldiers who know you to work with you. I am prouder than ever I was in belonging to a corps that can produce such true men. Well, owing to the kindness of Mr. Campbell, and of Colonel Burton, who was going to make eye-observations of the transit) tows up the river by a government tug, on which I placed my hut. The instruments I took on board my boat, stowing them, as you may imagine, with most jealous care; for I was going to a place where it was hard to purchase even a nail; all great repairs would have been hopeless.

We started on the 25th October from Cairo, our baggage (which had occupied three large trucks on the railway) distributed as I have indicated. On the 7th November we sighted Karnak just at sun-set, and a glorious vision it was. The old ruins seemed like rubies set in the dark, while the palms which rose between us and them, I certainly have never before been so impressed by any sight excepting, perhaps, by the first view of the Alps from the Jura, when there was no rail to Geneva, and where one had to go by diligence from Dole. It is really beyond word-painting, and certainly beyond the palette. The scene was soon over as the sun set, and we were nearly in darkness by the time we arrived at Luxor. The next morning we moored up against an island just above Luxor, and the same day began erecting our observatory. This wooden observatory is one which is well worthy of a study; it is so complete in itself. Each part was accurately fitted, and there was no driving of nails to put it together. Each piece was numbered, and had its own screws and bolts. The roof of the hut all took down, being hexagonal, each part could be put in a separate box according to the position of the sun. One fact worthy of record is this, that it was watertight, a quality usually absent from such erections. I had it nearly a year at Chatham before I took it to Egypt, and, to my knowledge, not a drop of rain entered it when the shutters were up. After using it so long at Chatham, the feeling of knowing every nook and corner in it was one of intense comfort. The only point in it which would have borne improvement was the dark room, which, for a hot climate, was just a little bit too small, being 8 feet by 4 or thereabouts. The internal arrangements were admirable for wet plates, and the additions I made for dry plates answered very well.

I will first give a sketch of the drying cupboard, certain improvements in it having been suggested by Corporal Sharpe, R.E. It was a box attached to the side of the wall of the dark room away from the developing-sink. It was divided into two portions in its length, and each length had a separate flap-door opening upwards, with a lock and key. In each compartment were two shelves, so that it would contain two rows of plates.

The plane of the plates as they stood up to dry was at right angles to the front of the box. The top corner was held by a triangular notch cut in a bar of wood, traversing from back to front. (There were many bars as the number of plates that the cupboard could hold.) The bottom corner for draining was held by a porcelain inkpots. The plates when drying were about two and a-half inches apart; and by this means about six dozen plates would be prepared at one working. The size of the plates was 6 by 6 patent plates, slightly ground at the edges.

It was a week before we set regularly to work; there was so much preparation in adjusting the instrument and getting chemicals, and so on, in order. I think it was on the 15th that we took our first sun-picture. We lived on board our boat, our Syrian dragonman Milmah Ouardy (a capital man, by-the-by, and fully up to his work) catering for us. Mutton, chickens, and pigeons were our principal diet. The keys and cement in the currently seized were used much for the time of opportunity. We took our own liquor with us, a supply of Tennant's beer being laid in for the alcohol-beer process. Though not strictly photographic, I will record our times of eating—coffee and eggs at eight, breakfast (really a lunch) at twelve, and dinner at six. We always got up before the sun, which was generally about six o'clock, and went to bed when our work permitted. Up the Nile one does not require so much sleep as at home, the air is so exhilarating. * Read before the Photographic Society of Great Britain.
bitter ale. Care should be taken that, by a gentle heat, the carboxylic acid is all liberated, otherwise carbonate of ammonia will be formed on the addition of alkaline albumen.

(i.) Any ordinary collodion will answer. The bromo-iodized sample supplied by Thomas of Pall Mall, with 2% of pyroxylene added to each ounce, gives very rapid results. For sun-pictures, however, a modification is advisable, as much will depend on the climate in which it has to be employed.

(ii.) For a cold climate, collodion made by the following formula will be found to give good results:—

Thomas's bromized collodion ... 20 ounces
ordinary bromo-iodised ... 20
Plain collodion, not iodised ... 6
Pyroxylene ... ... ... 270 grains
Water ... ... ... 400 minims

(iii.) For warmer climates the following will be found to answer better:—

Thomas's bromized collodion ... 20 ounces
bromo-iodised ... 20
*Altschul's exp. gr. -805 ... 6 on 8
Pyroxylene ... ... ... 300 grains
Water ... ... ... 120 minims
With (i.) the ordinary nitrate of silver bath, 40 grains to the ounce, is used. If greater sensitiveness is required, 10 grains of nitrate of uranium to each fluid ounce of the above are added.

With (ii.) and (iii.) the above bath should be used, together with another made 60 grains to the ounce of water.

A substratum to the collodion is recommended, to insure adherence of the film to the glass plate during development. This is made by mixing the white of one egg with 400 grains distilled water, and applying it to the surface of the plate by a piece of swan's down, calico, or flannel folded over the edge of a strip of glass and used as a brush. The brush is dipped in the fluid, and drawn down the plate in parallel lines till the whole surface has received a coating. Here I may mention that a clean plate is necessary; but much polishing with a silk handkerchief or chamois leather prevents the substratum taking kindly to the glass.

Another substratum, which seems to give almost better results than the albumen, may be substituted for the above:—

Sheet gelatine ... ... ... 75 grains
Distilled water ... ... ... 60 ounces
Ammonia ... ... ... ¼ ounce
Alcohol ... ... ... 1

The gelatine should be softened in 30 ounces of cold water, and then dissolved by 30 ounces of boiling water. When cold, the remaining ingredients should be added.

If a plate (after the substratum has been thoroughly dried) is coated with collodion (i.), it is sensitized in the ordinary manner in the 40-grain bath, i.e., for about four minutes in cold, to 2½ in warm weather. If the plate has been coated with (ii.) or (iii.), it is plunged in the 40-grain bath, and kept there till all "greasiness" has disappeared. It is then transferred to the 60-grain bath and kept there for seven or eight minutes longer, i.e., until a creamy film is obtained. The plate is next plunged into distilled water, or spring water; which has been rendered slightly alkaline by adding a few drops of ammonia to it (if iron be present as an impurity), and to which, after boiling and filtering, a few drops of nitric acid have been added to restore neutrality. When the "greasiness" has disappeared from the film, the plate may be washed under the tap for a minute, or in different dishes of water, until all free nitrate of silver is washed off. It may be affected rapidly by adding a pinch or two of common salt to the last washing water but one in the dishes. In a small tumbler are next mixed equal quantities of A and B, stirred up with a glass rod, and floated over the washed film. If

* The better the climate, the more alcohol will be required.

* Drawn up by request of Sir G. Airy in March, 1874, for the transit observers.

ELECTRO-PLATING BRASS WORK.

Dear Sir,—Every photographer must have had reason to deplore the destructive effect upon his camera of the solutions he uses: hinges drop to pieces, corners open (in the dark slide especially), and our friend the light, who, like fire, is a very bad master, becomes master in the wrong place. Brass binding mitigates the evil, but does not cure it, for the composite metal becomes soon more or less reduced to nitrates, screws get loose, and their heads come off.

As it does not yet appear to have been tried, I venture to suggest the simple plan of electro-plating the brass work with nickel; the process costs only about one-fourth the price of silver plating. The nickel coating will resist entirely the oxidizing influence of the sun, and sulphured hydrogen, and is comparatively but slightly affected by nitric acid, and not at all by any other acid likely to be employed.—Yours respectfully, P. Roza.

PROTECTING CAMERA SLIDES, ETC.

Sir,—Having used the varnish mentioned at foot in our picture framing department for Oxford and other wood frames for several years, I have been led to an old camera and slide which has lain by during the winter, and consequently looked decidedly seedy. The result is a presentable article, and an inward vow not to order a new camera just yet. Varnish for woodwork dries in the sun or warm room, being careful not to place the article varnished near a fire, as it will blister.

Orange shellac..... 2 ounces
Sandaro..... 1 ounce
Bensoin..... 
Rosin..... 

Methylated spirits of wine..... 1 pint

Place in a warm place, and shake. Archer Clarke.

Proceedings of Societies.

The Edinburgh Photographic Society gave another of its "Popular Evenings" in the Queen Street Hall, on Wednesday, the 17th inst., when, as usual, every available seat was occupied. The exhibition was entitled "Sketches of English Life and Scenery," and included pictures of several of the principal gardens and cities of the Horticultural Society, the Zoological Gardens and many of their tenants, and a large number of genre pictures illustrating various phases of English life, both grave and gay.

Dr. John Nicoll, who occupied the platform, commenced by saying: 'Those of you who have been in the habit of attending the popular meetings are aware that the committee who are charged with the arrangements have always tried to secure for each exhibition a series of connected pictures which should form a base on which to build a story and description of a tour, &c. In this way we have together, during the last dozen years, visited various parts of the world, including most of the grand scenery of our own land, generally with much pleasure, and sometimes, I hope, with profit also. To this rule, however, there has been one exception, when the experiment of a series of unconnected pictures was tried, being selections from the works of the best photographers throughout the country. The experiment was so successful that the committee resolved to risk another attempt in a somewhat similar direction. The exhibition of to-night, however, differs from that of the experiment alluded to, in so far as, while it consisted of landscapes, architecture, this is altogether, or almost altogether, of figure subjects. I say almost altogether, as I confess that at the eleventh hour I began to have some misgivings as to the result, and applied for a few pictures of a somewhat different kind. What I wish you to understand is simply this: that the pictures for the exhibition of to-night are of such a nature that each will speak for itself, and tell its own story—in fact, better than I can do—and that therefore I shall have little more to do than merely mention the titles, most of which you will find exceedingly appropriate, although you will please to remember that I have neither the responsibility nor the credit.
them, as I shall simply quote from the printed list. Before the room is darkened, I wish to take the opportunity of saying that the members of the Society—and I may say, also, the friends who have honoured us with their presence—are much indebted to Mr. York, of Notting Hill, London, who, in the most literal sense of the word, has adorned his fine specimens of paintings and lantern pictures at our disposal. The transparencies are all produced by himself, and the figure subjects from negatives by Mr. Gille, of Bridgewater. Some of our members know a little of the difficulties encountered in photographing babies, and will have been struck by the striking beauty of Mr. York's process. I had with in getting the negatives of the inhabitants of the Zoological Gardens, and they will, I am certain, when they see the results, agree with me in saying that he has succeeded beyond what could have been thought possible. The pictures by Mr. Gille prove him to be an artist of no mean ability, and a photographer of great technical skill, and at the same time give abundant evidence that in skilful hands photography can be readily raised to the dignity of high or fine art.

The pictures were then projected on the screen, and formed a most delightful exhibition, which, with the running commentary of the lecturer, kept the audience in a continuous state of laughter during its whole course.

Talk in the Studio.

Obscene Photographs.—At the Middlesex Sessions, before Mr. Edloe, Q.C., Assistant-Judge, Charles Uffix, 31, hawker, pleaded guilty to selling a large quantity of obscene photographs, which he procured for himself. Mr. F. H. Lewis appeared for the prisoner. Mr. Cooper said that this was the first occasion on which the Society had taken up the prosecution of such a case as this. It had been ascertained, from a letter found at the prisoner's premises, that he had been selling the papers since November last. Mr. F. H. Lewis said that a short time since proceedings had been taken at the Mansion House against the prisoner for selling pirated photographs of engravings published by Messrs. Graves, and, on the officers going to the premises, they found the papers. He thought it would be as well to recall that the proceedings had been carried on the business for so long a period as that mentioned by the prosecution,—The Assistant-Judge passed sentence of twelve months' imprisonment with hard labour.

More Obscene Photographs.—At the same sessions William Oliver, 28, picture frame maker, pleaded guilty to unlawfully publishing and selling indecent prints. Mr. Besley said that in 1873 there was gradually springing up in London a sale of photographs which were of so obscene a character that the Society took the Suppression of Vice fell to the Caroline of the carbonte of socede will produce as a result of the remarkably. If the night is not sufficiently clear, or the chemicals are not in sufficiently good order to secure an instantaneous picture, the image of the moon will, of course, be formed from its movement, unless, by some contrivance, you make the camera move more gently and regularly, following the movement of the moon.

B. M. F.—If your pyroxylene tends to give a somewhat thick, glutinous collodion with a tough film, the iodide and bromide of calcium will increase that tendency, whilst the use of ammonium salts will reduce the tendency. With the latter, the collodion will more quickly ripen, and as it ripens the collodion becomes less glutinous, and the film loses touch and hardness.

The addition of a few drops of tincture of iodide to a new, colourless collodion will often enable it to be worked without fog. 3. We, as a rule, prefer equal parts of ether and alcohol. In our own practice we have found no disadvantage arise from the use of methyl ether and alcohol. Ether and alcohol are different, and the use of alcohol and ether are different, but the use of alcohol and ether is different. The former is wo'd spirit, the latter is ordinary alcohol to which ten per cent. of methyl alcohol has been added, with which addition—because it is used for staining purposes, it is permitted to be sold without payment of duty. Methylated ether is other manufactured from methylated spirits.

L. D. — The refuse of your gold bath to tone, and the dirty brown colour it has assumed, are suggestive of decomposition caused by touching it with fingers which have been immersed in the fixing, or in contact with hypo in some form. The print enclosed is sure to have been exposed with a hypo at some time; it succumbed before toning in a dish which has probably been used for washing prints after toning, and, therefore, traces of hypo about it. Are you careful to keep each dish to its own use? An unfiltered print should never be placed in a dish which has had the T. ARNAUD DE RIVIERE.—Waste of iron, or waste of iron in conjunction with sulphate of iron, used as a developer for negative, gives greater intensity and a somewhat more non-acidic colour than sulphate of iron alone. The process of preparing the solution is as follows: Take a litre of water; mix the two solutions, and filter out the white precipitate of sulphate of lead; then add a ten minims of acetic acid, and the solution is fit for use. Or dissolve twelve grains of sulphate of iron in a glass of soda and six grains of acetic acid, and two or three drops of liquid ammoniac, which will be sufficient to reduce the solution into acetic of iron. Alcohol may be added in any case to aid the flowing freely of the solution, at the pleasure of the operator; but, of course, the alcohol only possesses this mechanical value. We leave it all to the developer.

B. W. H.—The addition of excess of nitric acid will sometimes cause fog, but it is probable that the water employed in making the bath has been contaminated with some organic matter, in which case a thorough standing—fall, boiling—will probably be the best remedy; or you may test it with a solution of permanganate of potash. Take a ten-grain solution and add a few drops more, shaking each time, and allowing an interval of (say) ten minutes between each addition. If a faint pink observable tint remains, the organic matter is removed, and you may filter, and try a plate.

LUNAR.—Your inquiry as to where information on "night photography" and "moon photography" may be obtained appears somewhat indefinite. Do you mean by this astronomical photography in which a telescope is used, or simply how small images of the moon may be obtained in the ordinary camera? We have published many papers on astronomical photography. In our fifth volume, pp. 17 and 31, you will find much interesting information on lunar photography. But if you refer simply to cameras on the moon, we do not remember at the moment that anything has been published, except incidentally. There is not, in fact, much to say on the subject. A bright, clear night, with the moon shining brightly, and the ordinary wet process, will enable you to secure an instantaneous picture. If the image of the moon will, of course, be formed from its movement, unless, by some contrivance, you make the camera move more gently and regularly, following the movement of the moon.

E. E. (No. 1.)—The precipitate was double and a mixture of the carboante of silver and aurum. On neutralizing a bath with carbonate of soda it is useless to test it with litmus paper until it has stood some time, because the carbonate of soda will produce as a result of the remarkably. If the night is not sufficiently clear, or the chemicals are not in sufficiently good order to secure an instantaneous picture, the image of the moon will, of course, be formed from its movement, unless, by some contrivance, you make the camera move more gently and regularly, following the movement of the moon.

B. M. F.—If your pyroxylene tends to give a somewhat thick, glutinous collodion with a tough film, the iodide and bromide of calcium will increase that tendency, whilst the use of ammonium salts will reduce the tendency. With the latter, the collodion will more quickly ripen, and as it ripens the collodion becomes less glutinous, and the film loses touch and hardness.

The addition of a few drops of tincture of iodide to a new, colourless collodion will often enable it to be worked without fog. 3. We, as a rule, prefer equal parts of ether and alcohol. In our own practice we have found no disadvantage arise from the use of methyl ether and alcohol. Ether and alcohol are different, and the use of alcohol and ether are different, but the use of alcohol and ether is different. The former is wo'd spirit, the latter is ordinary alcohol to which ten per cent. of methyl alcohol has been added, with which addition—because it is used for staining purposes, it is permitted to be sold without payment of duty. Methylated ether is other manufactured from methylated spirits.

L. Alcohol may be added in any case to aid the flowing freely of the solution, at the pleasure of the operator; but, of course, the alcohol only possesses this mechanical value. We leave it all to the developer.
PHOTOGRAPHY IN AND OUT OF THE STUDIO.

PROGRESS IN PHOTO-ENAMELLING.—HONOURS TO PHOTOGRAPHERS IN BERLIN.

Progress in Photo-Enamelling.—Like his brother the late Prince Consort, the Duke of Sax Coburg Gotha takes a lively interest in art matters, and we see that very recently he has paid some attention to that beautiful branch of our art, enamel photography. There cannot be a doubt that these charming pictures will take the highest place in photographic portraiture, and one may safely rely upon good enamels never becoming very common. The Duke of Sax Coburg, it appears, has been struck with some fine productions of this kind produced by a German artist, M. Stender, of Hanover, and in order to encourage further work in this direction, and to promote the production of imperishable photographs in this charming form, his Highness has conferred the Gotha medal for art and science upon M. Stender. We are glad of this for two reasons: it shows how highly the art-science is esteemed by one of the best authorities on such matters in Europe, and it will moreover serve as a great incentive to others to perfect the process as much as possible. Fortunately for the better class of photographers, the preparation of photo-enamels can never be practised except by those who systematically work up the subject, and possess considerable experience and taste. We shall never see photo-enamels selling at five shillings a dozen, neither is it likely that ill-executed productions of this kind will find many buyers at all. Only if an enamel is really first-rate will it sell at a sufficiently high rate to compensate one for its production. It is only those who have tried the experiment know how difficult the production of perfect enamels is. At Limoges, whose enamels were famous centuries ago, the art has been completely lost, and one of the professors at the Polytechnic School of that town recorded that the art had been revived among the townsmen, employing photography, however, instead of painting, as in days gone by. There seems, however, to be no information extant, either of a written or printed character, for the old Limoges enamellers seem to have passed their knowledge of the art on from one generation to another without committing any of their experiences to paper. So the learned professor finds it necessary to revive the name of Limoges enamels, the only way is to begin from the beginning as all photographers have been compelled to, and work step by step through the delicate process. Many have inveighed against the art because there is always a lack of certainty in its results; but this uncertainty is not only inherent to photo-enamels, but has existed ever since the commencement of the art of enamelling, and constitutes, indeed, one of the main reasons why enamels of all kinds are so rare and sought after. The delicacy of the burning-in operations, and the chance of success that attend them, are phases in the preparation of those charming productions which cannot be regarded altogether as drawbacks. In the same way as in the olden time the casting of a bell was always attended with doubt and difficulty, so we portray in Schiller's well known Lay of the Bell, so photographic enamels can never be predicted as safely finished until they have gone through the very last operation. But then there is all the more cause for congratulation when the risky business is over, and all one's cares and troubles are ended; the fruits of one's labours and the result of several trials being centred in the shining enamel before us. Every operation has been carefully watched and cautiously conducted, and three times, probably, have you committed the delicate picture to the tender mercies of a fiery furnace; for it is only after the image has been fluxed and cooled that the work can be said to be finished. How eagerly you wait that last operation of all! A soft but vigorous portrait has been produced so far upon the white tablet; you pour upon it the flux, and proceed to burn-in for the last time. The tablet is put upon a bit of clay near the glowing furnace to warm, then turned round to be heated throughout; then the image is approached nearer and nearer until you consider it may be safely introduced into the entrance of the furnace. As it is pushed farther and farther into the interior, the portrait gradually disappears from view, and nothing is seen for some time beyond a dull reddish surface; presently the picture begins again to reappear, this time covered with a vivid gloss, which, acting like a transparent varnish, adds redundant brilliancy to the picture. Gradually the tablet is withdrawn, gently it is allowed to cool beside the furnace, and in another five minutes you may rejoice in the success of your work and the end of your labours.

Honours to Photographers in Berlin.—Referring to honours conferred upon photographers abroad, it is satisfactory to find the same falling upon worthy heads. In Germany we find it rare for any photographers to make their mark in one of the bigger cities without some recognition from royalty, and such men as Fritz Luckhardt, of Vienna, and Albert, of Munich, do not remain long unrecognised. Either a medal is given in cases of this kind, or the title of Court Photographer, which is worth having, under imperial rule. We notice that the well known portraitist, Messrs. Loecher and Petch, of Berlin, whose works are widely known throughout Europe, have had the rank conferred upon them by the Emperor of Germany in the same way as the gentlemen previously mentioned enjoy the title from the Emperor of Austria and King of Bavaria respectively. Another firm, M. W. Fechner, also a Berlin photographer, has, it appears, also been the recipient of honours lately, but in this case they came from the Emperor of Japan, who forwarded a costly pair of Japanese vases as a present to M. Fechner, in return for an album containing portraits of a party of Japanese youths who are now studying in Berlin. What, however, we were most glad to hear, in the shape of honours from Germany, was the news recently published of our friend Dr. Vogel, of Berlin, being given a chair at the Industrial College of Berlin, where he has been for a long time lecturer and instructor in photography. On his return from India, where he has gone at the invitation of the Royal Society of Great Britain, in company with Mr. Schuster and M. Jansen, to watch the approaching eclipse of the sun, his services will doubtless not be forgotten, either in this country or his own.

DULL DAYS.*

For many years past we have not had such a dull winter as the present one. Since the end of November, 1874, we have lived in a state of sun-eclipse. Sometimes, on rare occasions, the solar orb has shown itself for a couple of hours in the forenoon, but it is soon crept back again behind the clouds, and hid itself more obscurely than ever; so that by the time you had sensitized a batch of paper ready for printing, your chance was gone, and the sensitized material became yellow and useless by keeping. Many a day there was scarcely a print per negative to be had, and this, too, about Christmas, or New Year, when one always finds a little ready money very handy. But nothing could be done. It was all very well to say, "Never mind, as Japan sunny we shall get brighter weather," but it never came. You might watch the barometer and thermometer as much as you liked, and deduce the most favourable results from the data they furnished, but, for all that, the weather remained dull, grey, and wretched.

That no work could be done for Christmas customers is not to be wondered at. With a shake of the head, I inspect my December work. There are all in one under-exposed, notwithstanding the flood of top-light which I

* Photographische Notizen.
had to use, and which made my models appear hollow
eyed; all seem to regard me with a sinister expression, as
if it were my fault they are so unhappily depicted. But
what could I do? I can draw back my blinds, but I
cannot draw back my eyes after the sun has risen and the
lines long enough to reach up there have still to be discovered.
The only consolation you have is, that all of us are in the
same boat, whether we are court photographers or not.

It is very obvious that one cannot undertake any fancy
lighting of the sitter in such dull weather. To attempt to
secure Rembrandt or any other effects would be madness,
even if one gets visits from ladies every now and then
who desire to be depicted in that style and no other.
You may draw back your blinds to their utmost extent,
and light up farther with mirrors and reflectors, but
such negatives, when developed, always turn out grey and
extremely thin, so as to require very much intensifying
before being fit for use. Brilliance may be obtained by
carrying on the intensifying operation for some time, and
a better print is then secured than can be got from a thin,
grey negative. The clichés need not be so vigorous as in
summer, and they print, indeed, much better in the dull
light we are having.

As regards collodionising the plate, you very often fall
into the error of pouring the liquid too thin, and this is
just the reverse of what should be done. Winter plates
always need more agitation, for only then do you get excited sensitiveness. You may allow the
collodion to flow several times up and down the plate
before it is drained off, and in this way a much thicker, and consequently more sensitive, film is secured. Rather
more ether should be contained in winter collodion, so
that if you are in the habit (say) of mixing your solvents
in the proportion of—

| Alcohol | ... | ... | ... | 75 parts |
| Ether   | ... | ... | ... | 45     |

when preparing collodion for ordinary work for the spring
and summer, you may alter the proportions very profitably
to—

| Alcohol | ... | ... | ... | 60 parts |
| Ether   | ... | ... | ... | 60     |

when preparing the collodion for winter use. Good recei
tives may be found in Vogel's Handbook.

Very important is the condition of the silver bath in
winter. Everybody knows that, in the first place, the
operation of sensitizing takes a long time when the bath
is cold. It is therefore ridiculous to follow such people's
advice who tell you always to sensitise for a period of two
months. You should introduce your plates into your
silver solution until all marks of greasiness over its surface
have disappeared. I will not assert that the temperature
interferes with the sensitiveness, but one thing is very
certain: that far more alcohol and ether get into the
bath in winter time than in summer. I sensitise in a
horizontal dish, and I have merely to allow the bath
to remain uncovered during the night in summer time to
be rid of the spirit therein; but in winter this precaution
does not avail me, for the alcohol and ether will not
evaporate. If the alcohol should not happen to be abso-
lutely pure, then it follows as a matter of course that a
bath may get out of order in winter through the effects of
cold, as it does in summer from the effects of heat.
Organic substances are seen to accumulate on the plates.
At first they are taken for streaks in the direction of the
dip, for they all assume this position, and do not dis-
appear on agitating the plate in the liquid. If the bath is
poured out into a flat dish, and the operation of sensi-
tizing is then proceeded with, the marks are still formed,
but they proceed from the four corners, and are bent
towards the middle of the plate. At the first they are of
so little importance that they make no impression upon
the prints, although a sharp operator will see them during
the process of development. Soon, however, a lack of
sensitiveness becomes gradually perceptible, and this is
the worst trait of winter photography. The best remedy
against this is permanganate of potash, for the assistance
of the sun in sunning the bath is not to be thought of.
One must be careful not to add too much permanganate to the bath. A drop should first be put in,
and then, if the reddish tint disappears rapidly, another
drop is added, and so on until you remark the red tint
imparted by the permanganate remains in the solution for
some time; finally, as many drops of nitric acid are added
as previously of the permanganate solution.

It must not be forgotten that in cold weather a warm
developer should be used, as it brings out more details than
a cold solution. A temperature of 15° Reaumur is the
best.

These are some of the points to be taken into considera-
tion in dull weather. It must be remembered, however,
that a quick-acting lens is one of the most important
things under the circumstances, for without an instrument
of this kind the best chemicals will avail little. Again, one
must sacrifice a little sharpness during dull weather, for to
employ stop in the camera when the light is bad amounts
to the same thing as drawing the curtains. Masterpieces
in the way of portrait photographs cannot be expected
under such disadvantageous circumstances.

THE PRACTICAL PRINTER IN AMERICA.

XXI.

TO ING BATHS.

Mr. Hearn rightly remarks that, of all parts of photo-
graphic printing, this is undoubtedly the most important
and difficult, with the exception, perhaps, of the manage-
ment of the printing bath; and he predicated his practical
hints by a few explanatory remarks, as follow:—

"There are a great variety of toning baths in use, a
great proportion of which are excellent for certain cases.
We shall here give our humble thoughts or ideas in the
making and care of the different toning baths, with such
quotations as may be found necessary from others probably
far more skilled in this branch than the author may be.

"Before proceeding further, I will explain to the
beginner the reason why there is such a bath, called 'the
toning bath,' used.

"The prints, as they were left in the last chapter, need
some agent to remove the silver left in them, else they
would continue to darken upon exposure to the light, and
in a short time be so dark as to be indistinguishable.
This agent is none other than hypo solution. If we want
to tone the prints as they are now directly into the hypo
solution, they would turn a dirty yellow colour, to get rid
of which and give a more pleasing one, a bath called, as
before said, 'the toning bath,' is made.

"Hence, then, the object of the toning bath is to give
partly permanence, but principally to give the colour or
tone to the prints, and in this colour we may expect to
find character, beauty and beauty, according as to how the prints
were treated while in the bath.

"In the first place, good chloride of gold is necessary in
the making of these toning baths, and to those persons
who do not wish to make their chloride of gold for them-
sewes, among whom the young beginner should certainly
be classed, I would advise them to purchase a stock
from some reputable toning manufactory. Each bottle contains fifteen
ounces, which may be dissolved in a bottle containing fifteen
ounces of pure filtered rain or distilled water. Label
this bottle, 'Stock gold solution, one grain to the ounce
of water.' This solution will be slightly acid, which it
should be, to prevent the light from precipitating the gold.
Keep this bottle in the dark, or at least out of the
brightest diffused light.

The formula for the acetate bath is well known, and
need not be repeated at length here. In its simplest form
it consists in dissolving one grain of chloride of gold in ten ounces of distilled water, and adding half a drachm of acetate of soda. The bath is fit for use in a few days, and may be used over and over, simply adding fresh solution from a stock bottle, made as at first, from time to time. It shall never be kept in the light. We may add both a brief explanation of the theory of this kind of this bath, which Mr. Hearn does not give. Chloride of gold as commonly sold contains a trace of free hydrochloric acid, the presence of which prevents its ready decomposition. To bring it into a suitable condition for toning, this hydrochloric acid need to be neutralized, as its presence would retard toning, and would also cause blotches over a brief explanation of the theory of the hydrochloric acid, having a greater affinity for the soda than the acetic acid with which the soda is allied, gradually decomposes the acetate, forming chloride of sodium, and liberating acetic acid. The latter does not injure the prints, and facilitates toning. As the reaction takes place slowly, a day or two at least should elapse before the mixture is used for toning. It should be remembered that a trace of free acetic acid is present in the acetate toning bath, and prints should always be rinsed after the toning, before immersion in the fixing bath, otherwise a slight decomposition of the hypo, with liberation of sulphur, to the detriment of the prints, will take place.

**SAL SODA** TONGING BATH.

Mr. Hearn, in using the carbonate of soda bath, uses a very large proportion of the alkali, as a saturated solution may be regarded as containing in round numbers 50 per cent. of the salt; hence he uses 120 grains of carbonate of soda to 3 grains of chloride of gold.

Distilled or boiled ice-water ....... 64 ounces

Acid sol. chloride of gold (4 grains to the ounce) ....... 1 ounce

Saturated solution sal soda ....... 1 ounce

“Toning bath feels quite slippery to the fingers. Make it a full half hour before you wish to use it, and during the cold weather make it with the water slightly warm. Make it every night, and save the old solution, and throw down the gold with protosulphate of iron.”

“This bath bleaches a little more than baths generally do, and so the prints should be printed quite dark. The prints when first placed in this bath will turn quite red after a minute or two, and later they have dissolved into turning red. Wash them closely, for they will now very soon commence to tone so that you will readily notice it, and when they have once commenced to border on the tone you desire, they will very quickly arrive at the proper stage.

“In toning disregard the shadows, but watch the highlights and half tones of the face, and when they just commence to look purplish, and the red look has disappeared, they are tone 1, and should be immediately removed to a dish of running water. The hair, draperies, &c., may not look to be toned, but they are.

“When you are fixing these prints they will turn a variety of colours before they turn the right one, and then when that colour to which you toned them you may be sure they are fixed.

**CHLORIDE OF LIME BATH.**

“With this bath pure whites and fine blacks can be obtained; such effects as are suitable for architectural drawings, pencil sketches, &c. It should be made forty-eight hours before use, and when about to use it add a little of the gold solution, also a little of the chloride of lime. There is considerable fault found with this, both on account of the uncertainty of its composition, and also with the various results obtained with it. That is owing to the photographer’s using what is called the saturated solution of the chloride of lime, when in many cases the solution is far short of being saturated. When you commence to make a saturated solution of this chloride of lime, and have placed nearly two ounces of the chloride in about twenty-five ounces of water, there will be a precipitate in the bottle which will make you think that the solution is saturated, since it will not dissolve the repeated shaking of the contents; but this is simply a part of its compound (the hydrate of lime), and you can still add more of the chloride of lime to the solution before it is saturated, as this chloride is separated and dissolved, whereas another part of its composition is not, for the beginner must bear in mind that the so-called chloride of lime is a compound.

The amateur who is still in the dark as to the use of this bath, and who is not aware of how to use it, will not find difficulty in using this bath, and to obviate we recommend that, instead of using a saturated solution, to accustom himself to weigh the chloride of lime, and then he can, after he has once started rightly, keep it always the same. This bath can be used a number of times by decanting the clear liquid out of the bottle and adding a little gold, enough to tone the prints, and a trifle of lime. It is made as follows:

Water ......... 64 ounces

Chloride of lime ....... 5 grains

Chloride of gold ....... 4 "

The chloride of gold may be made in strength at about one grain to the ounce of water, and may be neutralized with carbonate of lime, if it is acid. If the chloride of lime bath is made as above, we do not think that there will be any difficulty in working it.

(To be continued.)

---

**THE ART OF POPULAR ILLUSTRATION.**

**BY HENRY BLACKBURN.**

Besides the photographic processes there is the well-known French system of drawing on lithographic transfer paper, or on stone, from which relief blocks for printing with type are quickly obtained. This is largely used in France and England for periodical illustration of the “butterfly” kind, and as a substitute for the common kinds of engraving. There is also the system of drawing on wood plates with an etching needle, which has been known for ten years, but which has only lately made much advance. In the Portfolio there have appeared some artistic etchings by Alfred Dawson, printed with the type; and the process is now largely used both in books and newspapers. This system, however, requires special knowledge and practice on teaching and handling of the sciences, the results obtained (I believe it can be learnt in a week), produces the sharpest and best results—in fact, the nearest approach to wood engraving we have yet seen.

These two last processes are, I believe, the most suitable for making rapid illustrations for books and newspapers, it being now quite possible to make a drawing by these means at six in the evening and publish it next morning in a newspaper. That the blocks print well, and are in sufficient relief for working, on cylinder machines, you will be able to judge by the specimens in the room. There are yet other relief processes, some of which, like the “Graphotype,” have been known for years, and it is unnecessary to describe them. The reason for calling attention to processes generally is this, that owing to the perfection of the beautiful system of electrotyping the "fac-simile," such as the Autotype, the Heliotype, the Woodbury, and others, but as they are not available for printing with type at ordinary presses, I will not

---

* The term Sal Soda is commonly used in America to designate common carbonate of soda, NaO CO+10 Ag.—Ed. Phot. News.

* Continued from page 149.
refer to them rather than to express surprise that they are not more utilized for the immediate reproduction of paintings, drawings, and sketches. On the Continent it is generally the artist's first thought to prepare a copy of his picture in monochrome on purpose for the camera, so that accurate copies are obtainable simultaneously with the completion of the original. The facilities for copying pictures photographically are only half-developed in this country, and the result is this, that works that would instruct and delight the public, pass direct from the studio to the lonely halls of a mansion in some private park. Not one in fifty of our best pictures are seen by the people they happen to be exhibited for three months at Burlington House.

I shall be reminded, perhaps, that the engraver's art and the etcher's art have supplied and are supplying the public with copies of our best pictures, and, in fact, "meet the public want." But a good steel engraving takes years to produce, and is never an exact fac-simile. Some of the plates in the Art Journal, for instance, take eighteen months to produce. Consider this: a journal of art in the latter part of the nineteenth century taking more than a year to present its readers with a copy of a picture! I am thinking at the moment more of the title, and what a real Art Journal might be with the present facilities of reproduction at command. The excellent publication which bears this name, and in which fac-similes of Sir Edwin Landseer's works are now appearing, hits at exactly the public taste, and need not be disturbed, for it is doing good and useful work; but my theory of an "art journal" is a paper that should present to its readers, in some pictorial form, monthly (or weekly would be better) the artistic events of the day, and give in outline (on some such plan as I have suggested) an idea of the composition and scoring lines of every new picture as soon as it is exhibited.

Let us not be blind to the fact that the public is, as a rule, either impatient or indifferent; that if you do not give it a good thing quickly, it will take a bad one. We who have only a few years to live, and many of us really only a few hours left to devote to art, cannot rest content with a process that reproduces one work in two or three years. If the original is in this room to-night, but it has a picture if he will, and if his health and enthusiasm hold out well; but for reproduction in the press let us use the quickest and most method that science can now supply. That method at the present moment seems to be wood-engraving; which, in its quality of work, aided by good printing, almost approaches steel. Looking at the wood-engravings in the leading illustrated newspapers and at the publications of such houses as the Messrs. Cassell (I mention them because they represent, perhaps, the distribution of the largest numbers of cheap and good pictures), there would seem little left to be done. But we are moving on, and on, I believe, to a more artistic period still, when, by the power of photography, we shall attain far more simplicity and truth in popular illustration.

Mr. Guernsey, in his valuable work, upon the growth and progress of photography, has not only given an account of the development of the art during the last fifty years, but has also added much of interest and information. The necessity of running every word and thought into uniform lines has actually cramped and limited our powers of expression and of communicating ideas to each other. The child of three years old endeavours to express itself pictorially, but when it puts forth its hand to draw, there is no one to guide it. It has been born in an age of advanced civilisation, which knows no method of expression for the young but one—"pothooks and hangers"—and so for seven years of its growing life the subtle fingers are cramped to the achievement of parallel lines; and when the day comes to "learn to draw," say at ten years old, the delicate index is less sensitive, and much of the freedom and power of expression by the hand has gone for ever. That is not only the case of most of us in this room, but happily no longer so with the young; therefore there is hope that, even in our generation, we may see a great advance.

With the means now at command for reproducing any lines drawn or written in perfect fac-simile, mounted on squared blocks to range with the type, giving little or no trouble to the printer to tie the printers, is the handwork of the author and the artist appearing on our pages. We need not fear the multiplication of much crude amateur work by these means—our publishers will take care of that—but we should infuse more character and originality into every publication that comes from the press; and when I speak of originality, I refer specially to the originality of the author. The fact is, that in all the books, but especially in the books on art, and"editions of luxury," we are too neat and tidy. We fall submissively into the same mechanical toils, our noblest thoughts are printed like our weakest, and are all run out in lines together, as in the making of maccaroni. I fancy the editor of that most artistic periodical, the Portfolio, must oftentimes feel under the mechanical restraints imposed upon him. I think what he is interested in is an artistic craft, rather than an art in the direction of the problems presented to his papers on "The Sylvan Year" if a spray of grass, or leaf, or rare flower had been permitted upon the page— if it had not been swept so clean, if its forest walks had not been so highly rolled.

It is all a question of fashion, but the fashion may change suddenly, and a call be made upon us to produce more beautiful books. It is a question of money; but if we cultivate more systematically in our schools the art of drawing for the press, and treat it as a worthy profession. Let it not be said again, as it was to me to-day by one who has devoted half a life to these things, "The processes of reproduction are to hand: where are your artists?" There is the talent amongst us, the power of expressing ourselves pictorially to a much greater extent than is possible in the room to-night, but it plays about us like summer lightning, whereas we want the precision and accuracy of the telegraph.

In conclusion, shall it be said of our artists that the chariot wheels of the press move too fast for them—that chemistry and the sun's rays have been utilized too soon—that, in short, the processes of reproduction have been perfected before their time? I think not, and that an art which has existed for ages, and is now best understood by the Japanese, may be cultivated amongst us to a more practical end.

PHOTOGRAPHIC OPERATIONS IN EGYPT IN CONNECTION WITH THE LATE TRANSIT OF VENUS.

BY CAPTAIN ABNEY.*

Some gentlemen apparently seem to find this albumen-beer process not answer, and say it is the beer. I cannot say if it be the cause; all I can say is, that any beer seems to give me equally good results, and I have tried many. One thing, I think, may affect sensitiveness, and that is the collodion. I make mine rotten with water, and then add the same unwatered collodion to it till all "crappiness" disappears from the film. I lay great stress upon this point, as I believe the constitution of the pyroxyline is altered by it, and certainly the film becomes more porous. At all events, at Chatham the process is a general favourite with the men and officers; and we stick to it, as we find it the most manageable, and the easiest to teach.

* Continued from page 144.
I am not aware who introduced the gelatine* substratum as it stands. I know it has often been tried before, and failed to give satisfaction. When used with a Blanchard brush, it is first-rate.

Such is the process adopted at all stations belonging to the British expeditions, and I hear that it has been carried out most successfully and with less drawbacks than I had in Egypt.

On the day of the transit we exposed a plate about every one and a-half minute during the transit, beginning about twenty minutes after sunrise, and finishing twelve minutes before internal contact. This gave us about forty plates to develop, we exposed about forty-five. Just before internal contact, the slabs which carried the plate, and placed ready in position, was exposed. As you are aware, each plate is made to bear fifty different impressions, at intervals of one second of time; and, by so doing, very small differences of interval between the limb of Venus and the sun are obtained, and will be used for micrometric measurements. As the time of each exposure is accurately known, the results will be valuable. M. Janssen had the credit of first publicly proposing this plan, though it is a method that would have struck any one who was accustomed to a repeating back in a camera. Mr. Christie designed the form we used, and very ingenious it is. Mr. Dallmayr carried out the design with his usual ability. More Janssen plates were exposed in the interval between internal contact, and the contact and the measurement of the crescent will be very valuable. The small difference in apparent places of the sun and Venus being magnified largely as the limb of the latter is just leaving the former.

The manner we carried out our arrangements during the time was this:—We had six slides and twelve boxes to hold six plates each. These were all lettered, and each plate, that would be exposed, was numbered from 1 to 6. The whole of the slides, which were numbered from 1 to 6 as well, were filled from one box by one man inside the dark room, and passed out to the Sapper attending on me. As each plate was exposed, it was passed into the dark room through a different aperture, taken out of the slide by a second Sapper in the dark room, placed in its own groove, and the slide passed to be filled from the next box. I can remember the slides in the photothepist box, exposed each plate, taking up the time from my chronometer, and registered the number of the plate as shown on the back, together with the exact time of exposure. The first, thirteenth, and every twelfth plate after were developed during the transit, and the time of exposure was regulated according to the appearance of the image. Naturally as well, the plates got shorter exposure than they did near sunrise. When we first saw Venus on the sun's disk she was most unsteady; one photograph shows her as a square with rounded corners. The atmosphere was anything but still, the limb of the sun till very nearly internal contact appearing to boil. A fact worthy of remark is, that with dry plates, with the same exposure, the irregularity caused by this atmospheric disturbance is much diminished; for, dealing with the negatives, I cannot assign a reason for it which is too long to enter into here.

Directly after the transit had finished, the remaining plates were developed. This operation took till the evening. I believe the pictures we brought back have given satisfaction to the Astronomer-Royal, and no higher meed of praise do I desire. From first to last I have found it my task to work for that distinguished gentleman, his clear conception, grasp of mind, and accuracy of thought, invariably helping me in any difficulties that have arisen.

From our President I received the greatest encouragement at Greenwich.

It is rather the fashion to despise military routine; but I can honestly say that had it not been for military discipline and drill—krismos drill—I believe I could not have carried out all that I desired; as it was, the only hitch on the day that occurred was my fault, and not that of any of my subordinates. It was not a great matter, simply forgetting, in one instance, a word of command. As it happened, the mistake was advantageous, as I got a result which I should otherwise not have obtained. The transit-day over, we took two or three days of rest. Personally I was glad of it, as I believe even the most placid of men would suffer from the excitement of two hours' intense strain on the nerves. Much had still to be done in the way of making duplicates of the negatives; and here we encountered much difficulty. Transparencies are generally easy to make; but, owing to the necessary thinness of the negatives, we found it no easy task.* At length I had to come to the conclusion that the whole negative must be mounted on the image on the dry plate prepared as above. The sun appeared to be on unaltered bromo-iodide, whilst the sky was quite strong by reflected light. I then intensified with a wash of—

Pyro ....... 1 grain
Citric acid ... 20 grains

with two or three drops of 20-grain solution of silver

This answered admirably for our purpose, and the sharpness is fairly equal to the original. These transparencies we accomplished in a cruise we took up the river, when we paid a flying visit to Assuan, the First Cataract, and Philae, getting back to Thebes for Christmas Day. I picked up the butt of a souvemone—cigarette. It was the first present I received from my homewards on December 27. It was an unexciting process floating down the stream back again to Cairo, though helped by eight oars. However, we found plenty to do in packing up our small traps; and we reached Cairo on January 3. I have not touched on other photographic work than that of the transit of Venus. There is another matter I should like to mention, a long number of days I spent at the Suez Canal. I was the first European to enter into that subject. Suffice it to say that the Nile voyage, undertaken with a view to photography alone, is most enjoyable. Egypt is delightful in almost everything except in the system of backasheesh and in mosquitos, and these latter you lose at Thebes.

I cannot close this paper without referring to the kindness we received from the authorities. The Khedive gave us everything we required; he travelled with me personally Suez to Cairo, and back from Cairo to Suez; he gave us guards, tents, and police; he put at our disposal a steamer, and aided us in every possible way, even allowing us the free use of the telegraph for about fourteen hours to obtain our longitude at Thebes. The Eastern Telegraph managers, Mr. Gibbes and Mr. Cross, were simply invaluable. Mr. George was it was the first Egyptian telegraphers, sent to great personal inconvenience to us in getting through our time-signals. I have been officially in several foreign countries, and certainly never met with so much courtesy as we received in Egypt. Captain Browne, the head of the expedition at Cairo, reports equally favourably; and the English Government, I fancy, have given an official acknowledgment of it. Our whole action has been under the authority of the Egyptian Government. I think the Khedive and his Ministers more heartily congratulated us than they did. Never were expeditions more carefully planned and organized than they were by Sir G. Airy; and though, perhaps, rather expensive, I know I am right in saying that there was no breakdown due to anybody connected with it.

Although New Zealand was unfortunate, I am sure my brother officers there were as well (if not better) prepared than the rest of us.

* The negatives were necessarily thin to allow of measurement.
REJLANDER MEMORIAL FUND.

A brief announcement in our business columns informs photographers that a committee has been constituted for the purpose of receiving subscriptions towards a fund tributary to the memory of the late O. G. Rejlander. As we know that there are many of our readers who will gladly contribute to a fund for the purpose in view, we shall very briefly explain the object contemplated. Mr. Rejlander, as most photographers know, was not successful in a pecuniary sense. A passionate lover of his art, he was at all times more earnestly engaged in developing and illustrating its pictorial possibilities, than in securing the legitimate pecuniary results of such work. His wonderful fertility of invention, rare originality, admirable art knowledge and culture, great industry, and withal not a little of the feu sacré of genius, Mr. Rejlander did not possess the useful, if vulgar, faculty of making money. Without being regardless of business, or negligent of business, he was not a business man; and so far as making a fortune was the end of his labours, he was a failure. His was the higher success by which photography, and all associated with it, gain, of elevating his art, of doing much of the noblest pictorial work possible in painting with sunbeams. It was impossible, with such fecundity as well as excellence of production as a study of portfolios illustrates, for the artist to have been absolutely impecunious; but the extent of his illness which was, Mr. Rejlander's death, which absolutely prevented work, whilst business obligations were accumulating, inevitably issued in pecuniary complications and embarrassment.

Mr. Rejlander left a widow, who was, fortunately, in photographic matters, a help-meet for him. In a dying request made to us personally, he referred to the monetary obligations which had accumulated during his illness, and to the future of his widow. If the one object for which he referred could be satisfied, and the peaceful possession of his photographic effects, especially the subject negatives, with the printing and publishing of which she was personally familiar, could be guaranteed to his wife, her future would, he thought, be fairly provided for; and he added a conviction that there were many photographers who would be glad to remembrance of him to aid in bringing about such a result.

We appeal, then, to photographers in a twofold sense. We ask those who knew and loved Mr. Rejlander, and those who admired his great genius, to contribute to place his widow in the position of honourable independence which she can secure by the continued printing and publishing of his works. And we ask all photographers to contribute to the fitting memorial which such a fund, and such disposal of it, will form, to one who did so much to elevate their art, who did so much to diffuse art feeling amongst photographers in teaching by example, showing what was pictorially possible in photography, and stimulating effort by the marvelously beautiful results which were produced in such prodigal succession for many years. Looking at the matter in this sense, there is possibly scarcely a photographer who is not indebted to Mr. Rejlander. If a tithe of these debts be discharged, an ample fund, worthy of Rejlander's name, and in every way adequate to the fulfilment of his wishes in regard to the widow, lady he left behind; the obituary committee, to whom Sir Coutts Lindsay, Bart., the friend and patron of Rejlander, is Chairman; Mr. F. W. Mills, Secretary; and Mr. H. Baden Pritchard, Treasurer, is already formed; but the co-operation of other gentlemen who knew and admired Rejlander, especially some in the North, is desired, and the Committee will gladly hear from any who are interested in the matter. Contributions should be forwarded to Mr. Pritchard, at the Chemical Department of the Arsenal, Woolwich. The names of a complete committee will in due time be announced.

OBITUARY.—THOMAS SUTTON, B.A.

We announce, with deep regret, the death of a gentleman whose name, for upwards of twenty years past, has been one of the most familiar to all readers of photographic literature. After a very successful career Mr. T. Sutton died on the fourteenth of March, in the fifty-sixth year of his age. For some years past Mr. Sutton's health has been considerably shaken. Upwards of twelve months ago he informed us that he had been, for some time a constant sufferer from dyspepsia, the symptoms of which had been, we understand, considerably aggravated for some time before his death, which was recorded only very recently. After weeks of continual illness he succumbed to a sudden seizure of cramp in the stomach, from which he was released by death in a few hours.

Son of a gentleman of scholarly tastes residing at Kensington, whose name was familiar to numismatists, Mr. Sutton was born and educated in the neighbourhood of London, having been at one time a pupil of the present esteemed president of the South London Photographic Society, the Rev. F. F. Statham, M.A. At Cambridge, as a member of Caius College, he was distinguished as an ardent student and good mathematician, and acquired his degree of B.A., taking position as twenty-seventh wrangler in 1846. In the following year he went to Jersey with a student with whom he was reading in the capacity of tutor, and there resided for several years. For some years he was engaged in photographic research and contribution to photographic literature. In 1856 he commenced the issue of a monthly journal entitled Photographic Notes, which, for some years, was conducted with great vigour and interest. This journal was finally merged into the Pictorial Photographer, which, after a struggling existence of a year or two, dropped out of existence. In 1861 Mr. Sutton was appointed successor to Mr. Hardwick, lecturer on photography at King's College, a position he resigned in a few months, finding residence amid the turmoil of the great metropolis uncongenial to his tastes and habits. He returned to Jersey, and subsequently resided at Redon, in Brittany, where he undertook the duties of French Correspondent to a weekly contemporary. For the last few months he had been residing in North Wales.

Our personal knowledge of Mr. Sutton commenced in 1859, when we visited him in Jersey, and commenced an intimate friendship, which was maintained for many years, although somewhat interrupted by the polemics and politics which, in the history of photography, have at times been unfortunately conducted with a degree of warmth altogether beyond the adequacy of the occasions. None know better than ourselves, and none can more willingly testify that he was a writer of great ability, and a keen,
ardent, and enthusiastic experimentalist, the varying and occasionally contradictory character of his utterances being largely due to this enthusiasm. He wrote with a degree of trenchant vigour which, whilst it always possessed a charm, at times, on polemical subjects, suggested a rancour which was by no means in keeping with his true intention. For many years the deceased gentleman personally was prepared by his study of some of his writings for the winning, genial, gentle, and frank modesty of his personal bearing.

But whilst his name is most familiar to photographers in connection with photographic literature, it will also be associated with many practical points in the progress of the art. Indeed, his name is now practically as well known as the name of any artist, and he has been, and is, to a great extent, the father of the system by which carbon or various other processes, and many of his improvements in ordinary printing were of great value at the time of their publication. His experiments in the manufacture of collodion, and his introduction of his alcoholic colloidon, did much to revolutionize the system in which a very large proportion of other—at one time considered nearly as sure to succeed—were made, and he was the first to secure attention for permanent printing, whether by carbon or various other processes, and many of his improvements in ordinary printing were of great value at the time of their publication. His experiments in the manufacture of pyroxyline issued in practical formula by far the most trustworthy of any at the time issued. Without entering into detail, it may be fairly said that, as an experimentalist in almost every department of photography, he left much on record in connection with all, which was read with interest and instruction, even by those who felt it necessary on many points to dissent from his conclusions.

"ANOTHER NEW SWINDLE."

A letter to a daily contemporary, the Standard, appeals a few days ago with the above heading, in which the writer goes to some lengths to suggest the necessity of the art in which all our readers are interested, and concludes, that the letter, which is addressed to the public, is somewhat amusing, to contemplate the indignation about so small a matter which induced the writer to send a letter to a daily contemporay in complaint or warning, and not less amusing to find that, with every facility to ascertain whether there was really any swindle intended, no such attempt appears to have been made. I will print the letter, which will best explain the ground of complaint.

To the Editor of the Standard.

Sir,—As you so kindly open your columns to warnings to those who are easily imposed upon, may I ask that you will give publicity to the following?

On the 22nd of February last, and several preceding and succeeding days, two itinerant photographers were in the neighbourhood of Saratov taking photographs of the different houses, with the ostensible view of enabling some new American process of photography. They made no charge for taking the photograph, only asking as a favour that the lady of the house or the children and servants would stand to make up the picture. Having obtained this favour and the photograph taken, it was an easy matter to induce the servants to bespeak copies, which of course had to be paid for at once. A receipt was given on the back of a card which bears a name and address, but it is intimated that no copies have ever been sent, and that letters sent to the address given meet with no response. I understand that many servants and others have been induced to part with their money, and I write this to ensure that it may be a warning to others not to be so foolish. I may add that in cases where payment was declared until copies were sent no copies have been sent.—Your obedient servant, J.

On reading this letter, two very obvious considerations present themselves. In the first place, a little reflection might have suggested to the letter writer the improbability of two photographers deriving any advantage by taking pictures of a room and its inmates, expending time and material in taking groups of the "lady of the house" and children, on the mere chance of inducing the "servants" to bespeak copies, and pay for them in advance. It is possible that some photographers may be enterprising enough to engage in piratical portraiture; but the notion of taking groups of the family on the chance of selling a few copies to servants, or even of obtaining the price of the prints without supplying them, does not seem a promising or probable form of speculation. But we are informed that a receipt was given on a business card, containing name and address, which it is not alleged were fictitious. This being so, where was the swindle? At worst there is a tardy performance of contract. That a few weeks should elapse in winter between receiving an order, even with cash in advance, and supplying prints, may be a grievance, but if it be regarded as evidence of intention to swindle, we fear that the reputation of many professional photographers will be in danger.

SIZE AND PROPORTION IN PORTRAITURE.

By Robert Faulkner.

The introduction of a new size for photographic portraiture, though not an event to be marked as a red-letter day in the calendar of photography, cannot but be interesting to those engaged in the production of pictures by the camera. The commercial aspect of the question has been considered, but its merits from a fine art point of view seem to have been forgotten or ignored. Yet, in my humble opinion, it is not a subject altogether unworthy of a little thought. Photographic writers are very apt to refer to the works of Vandyke, Reynolds, Gainsborough, and such luminaries in art, and this fact induces me to give a list of the sizes of the various canvases employed by those great men in the production of their portraits, viz.:

<table>
<thead>
<tr>
<th>Size</th>
<th>Inches</th>
<th>Feet</th>
</tr>
</thead>
<tbody>
<tr>
<td>Head</td>
<td>2 1/2</td>
<td>2</td>
</tr>
<tr>
<td>Three-quarter</td>
<td>6 1/2</td>
<td>2</td>
</tr>
<tr>
<td>Kit-kat</td>
<td>3</td>
<td>2</td>
</tr>
<tr>
<td>Small half-length</td>
<td>3</td>
<td>2</td>
</tr>
<tr>
<td>Half-length</td>
<td>4 1/2</td>
<td>3</td>
</tr>
<tr>
<td>Bishop's half-length</td>
<td>4</td>
<td>3</td>
</tr>
<tr>
<td>Whole-length sitting</td>
<td>6</td>
<td>5</td>
</tr>
<tr>
<td>Whole-length</td>
<td>7 1/2</td>
<td>6</td>
</tr>
<tr>
<td>Large whole-length</td>
<td>8 1/4</td>
<td>7</td>
</tr>
</tbody>
</table>

It if is conceded that the works of these artists are worthy of imitation, then, I think, the sizes they adopted should be the basis of the scale for the dimensions of our pictures. Exceptions might be found to some, but certainly three of them—the whole-length, half-length, three-quarter or head-size—should be scaled on the above standard. The magnitude of these proportions lies with the manufacturers. They appear to have come to the conclusion, that only one size is good for the purpose—and that size is the mean and lanky carte-de-visite. If you attempt to discuss the matter with a maker of photographic frames, he will rejoin, "We study the requirements of the public, and not the caprices of photographers. We find the frame and album manufacture sell well enough—that is sufficient for us."

These commercial despot forget that a good shaped frame or album has not yet been made, and consequently the public has not had an opportunity of escaping from the regulation pattern, and adopting a good thing. I may remind them that many people of refined taste repudiate albums altogether, preferring to keep their pictures in boxes. If, in spite of refined taste, manufacturers are to continue to produce albums containing three sizes, surely a medium size—similar to the cabinet, but larger—should be selected. This, although a little too wide for a whole-length, is admirably adapted for the half-length, three-quarter or head-size.

Our lawyers, the manufacturers, should have some pressure put upon them to ensure their adhering to the sizes selected, otherwise they will deviate a quarter of an inch one way or the other, as I have experienced more than once.

A writer on art has said: "Proportion is the basis of beauty." Again, "Excellence is made up of the little more or the little less" (1 quote from memory). These golden axioms apply with peculiar force to photography, which, being so poor in resources, should seize upon every judicial expedient to promote its excellence, even in the apparently trifling matter of the proportions of frames and mounts.
ALBUMEN AS A PRELIMINARY COAT FOR GLASS PLATES.

BY A. BORLAND.

In reading some of the articles in the News and Year-Book, I have been surprised to find that the writers of them speak disparagingly of, or altogether condemn, the use of a preliminary coat of albumen. My surprise has been great from the fact that I have had several years' experience in the use of a subrasum of albumen, and I have always found it trustworthy when properly applied.

Amongst the many sins laid to its charge I find the following:—First, that it is a prolific source of spots and streaks; second, that it increases the exposure in the camera; third, that when used as a preliminary coat for collodio-chloride pictures it is a cause of fading; fourthly, that it is not always possible to obtain fresh eggs, and that store eggs are not to be depended on. These are very strong objections, but still I think I shall be able to give a good answer to all of them.

To begin with the last first, I am happy to say that there is no need for running after fresh eggs, as the dried albumen of commerce answers the purpose quite as well when properly treated. My own plan of preparing a stock solution is as follows:—To one ounce of distilled water add one drachm of the dried albumen, and two or three drops of strong ammonia. The ammonia is not added for the purpose of making the albumen keep, but for the purpose of making it dissolve more completely. That it does so may be easily proved by omitting the ammonia, and, after the albumen has apparently all dissolved, allowing it to stand for an hour or two, when the albumen will be seen to have settled to the bottom, leaving the water almost clear. Now add the ammonia and shake slightly, and again allow to stand, and it will be seen that no change takes place. If the stock is wanted to keep, a few drops of carbolic acid may be added to each ounce of solution, and it will then keep for some time.

To the third objection I have to say that the evil is caused by using the albumen too strong, one ounce of the stock solution in about thirty ounces of water being quite strong enough to answer the purpose it is intended for—namely, to keep the film on the plate; and it does this so well that the picture may be washed until every trace of hypo used in fixing is removed, which cannot be done without great risk where no albumen is used.

But I think I hear some one say, That does not dispose of the albumen sale of silver formed in the film. My answer to this is that these prepared in this way may be exposed to strong sunlight for months, and no change can be seen after the most careful inspection, the film of albumen being so very thin that any discoloration from the effect of light is not perceptible, and the coat of collodion a good protection from atmospheric influences.

To the second objection I give the same answer as to the third; viz., too much albumen is used.

In answer to the first objection, I think I cannot do better than state in full my mode of operation in the application of a subrasum of albumen: and to those who will try it fairly I can promise the same success that I have always had with it. I may say, first of all, that my experience was gained whilst working as an operator in America, where it is used by almost every one. The firm I worked for provided a boy with the necessary duty, to clean glass; but although I superintended the work, I could not always depend upon having clean plates, although I believe the boy did the work as carefully as he could; but in this, as in cleaning glass by the ordinary method, there are many little things require attention which none but a person of experience can see the good of; and for this reason I determined to undertake the albumenizing of glass for my own use, and I found myself a gainer by the operation, as I hardly, indeed, had a dirty plate, or a film leave the glass afterwards—a matter of great importance when plates up to 14 by 17 are in constant use.

It is best to prepare enough at one time to last about a week, the following being the order in which I do the work:—In the morning, before commencing other work, put a drachm of albumen to soak in one ounce of distilled water, and add two or three drops of strong ammonia; it will be ready for use in the afternoon, when it must be added to about thirty ounces of tap water, and filtered through paper, when it is ready to be poured on the plates. If new plates are to be used, they should have the sharp edges taken off by drawing them over each other from corner to corner, after which they are put, one at a time, into a solution of sulphuric acid and water (about one ounce of acid to twenty ounces of water), and allowed to remain until the afternoon. If old varnished negatives are to be used, they are put into a strong solution of printer's lye, and allowed to remain for a day or so, and then taken out and rubbed over with a piece of rough felt, washed under the tap, and then put into the acid, the same as new glass. The albumen having been filtered into a beaker glass or graduate, a plate is taken from the acid solution, and, after giving it a slight rub on both sides with a piece of felt, it is washed well under the tap, and, after draining for a few seconds, it is placed on the tips of the fingers, and a small quantity of the albumen poured on to the plate and allowed to flow all over, which it does freely, driving the water that remains before it. Do not pour back into the beaker, but allow to run into the sink, and then pour on some more of the albumen, and repeat the process, until the plate is covered, being careful to let it run down the sides of the glass, so that it may not cause bubbles. Stand the plates in a rack where they will be free from dust. Be very careful, when putting them in the rack, not to take hold of the top corner, as doing so is sure to cause streaks across the plate. When quite dry, they may be stored in plate-boxes, or piled together in the usual way.

Plates prepared in this way will be found free from all spots and streaks that may be caused by the use of albumen; and the great freedom with which negatives may be washed after the various operations adds very much to the comfort of the operator, in removing all fear of the film leaving the glass, or from stains caused by insufficient washing where such fear exists, and there can be no doubt negatives that have been prepared in this way are much less liable to cracking of the film than those that have been but slightly washed.

I leave these few rambling remarks in the hands of the fraternity, and hope they may be of some service to all who read them.

A MATT VARNISH.*

BY ANTONIO BOOHER.

It is known that a film of normal collodion coloured with fuchsine gives the most delicate and uniform covering to a negative, and that by its use vigorous shadows may be produced, but not lights. I have found it very good for thin negatives and such as are of good quality, but the retouchers must handle the film carefully, as it is easily damaged. One mode of producing a matt coloured, tough, and permanent film, is to be found in negative varnish to which a little tartaric acid has been added, the mixture being shaken occasionally, and allowed to stand for some days. This somewhat rough varnish permits retouching with the greatest facility; lights may be put in, or the film may be scraped, no delicate handling of the basis being necessary. The mixture is not always certain when a commercial varnish is employed. It sometimes happens that waves are formed (if shellac is present), or the dried film shows white streaks, and when these are removed the surface underneath is glossy. Nevertheless a good result is secured in most cases. The best and most certain result is obtained by means of a mixture of normal collodion and commercial amber varnish;
the plain collodion is diluted with ether and alcohol until it contains three per cent. of pyroxylin; and so much amber varnish is added as will render the mixture somewhat darker than olive oil in colour. One cannot be too precise with the details, because the nature of the amber varnish obtained in commerce continually varies. The mixture is shaken, filtered through cotton-wool, and applied like ordinary collodion; it gives at first a dense, milky, and not very trustworthy film, but while drying the film becomes very pure and fine, and perfectly uniform in character, its surface being such as it would be impossible to produce upon ordinary glass, either by mechanical or chemical means. In the space of fifteen minutes after the varnish has been applied, the film is dry in an ordinary temperature, and may be worked upon with a little care. If, however, it is left to become thoroughly decolored, requiring less time to do so than ordinary varnish, it permits of the application of high lights, the firm basis allowing the pencil marks to be made with certainty and uniformity. That it permits of scraping, and that it withstands the influence of moisture and is a protection during the printing process, follow as matters of course.

Experiments with the colouring of this varnish, which is only necessary in very few cases, I have not carried far; but I may mention that a fair result may be secured by the use of gum tragacanth. Among the aniline colours there are a few that may be made use of. Fuchsin is decomposed in contact with amber, shellac, or other resins, into a disagreeable lavender blue, and coraline seems to exert an injurious influence upon the tone of the prints. The employment of aniline blue is not possible, because of its liability to change and its behaviour in reference to actinic light; and picric acid is useless from many reasons. There remain, therefore, only violet and green, or mixtures, or certain vegetable colours attached to it. The varnish, however, being not tinted with aniline blue, and thus made to yield a matt blue surface, which would no doubt be grateful to the retoucher's eyesight.

For negatives of large dimensions, which require a good covering, I employ thin paper—either tissue, French, vegetable, or even writing paper, according to circumstances. The reverse side of the negative is used, and the paper is stilettoed colourless with gum spirit. The varnish is then, however, mounted on the paper and then made to yield a transparent patch, and graphite or colours are applied for covering.

HOW TO AVOID UNNECESSARY WASTE OF SILVER AND GOLD.

BY E. Z. WEBSTER.

AGAIN, "after many days," I take up my pen to bring to a close the series of articles upon this subject.

A paper which I had prepared, showing the immense waste of time, effort, and paper which might be avoided in the printing department of photography, I feel constrained to omit, because I have already made myself rather prolix. We will take up the subject where the pictures are ready for the toning.

Without stopping to discuss the subject of toning baths, we will suppose that you are using the common bicarbonate, or sal soda, or any other toning bath which is generally thrown aside when the batch of prints is toned; now, instead of throwing it away, pour it into a bottle, and do the same next time, and again if necessary; by that time enough old toning solution has accumulated with which we can proceed to the next operation, which will be the fixing or hypo bath. Now, instead of using plain water, take the old toning solution, and make your fixing bath of that, and when the prints are fixed, pour off the solution into another bottle, a few crystals of hypo to insure saturation, and let it stand till the next batch of prints is ready, and use it again, and even once more if there be not sufficient old toning solution to make another. You need not be afraid of sulphur toning; make it strong, and keep it so. And when you are done with the old fixing or hypo solution for prints, pour it into the tray wherein your negatives are fixed. The tray should be at least 20 by 24 inches by 3 inches deep, made of wood if you like, and watertight, of course.

Here you have the routine; now we will go back and get the why and wherefore. The first place in which I think you should know the general rule for toning is about one grain of gold to one sheet of paper, but there always remains a good portion of the gold in the solution when you are done, and to utilize that gold we will put it into the hypo or fixing bath, where it adds to the depth and beauty of the toning, instead of allowing the raw saliva to destroy a portion of what the prints already contain, thereby obviating the necessity of carrying the first wash so far, and requiring less over-printing, and from one-third to one-half less gold.

Secondly.—By using the paper "fixing" solution in the negative "fixing" tray, the same is not only made to do double duty, but the silver contained therein has a beneficial effect upon the negative film, as it tends to prevent the soda from attacking the delicate detail in the negative, and leaves upon the surface an extremely thin translucent veil, which adds to the softness and beauty of the print.

Thirdly.—The negative fixing tray being large, several negatives can lie in the solution at once if necessary, and the broad surface of solution exposed accelerates evaporation, by which means the tray is kept in good working condition, by the additions from the print "fixing" solution, but sometimes you freshen the water occasionally getting too full, depending altogether upon the amount of water used in your toning and "fixing," and the state of the atmosphere. When the solution becomes syrupy, pour it off and precipitate the silver with some pieces of zinc, and submit the precipitate to the action of hydrochloric acid; wash the precipitate thoroughly, then reduce the nitric acid to ammonia, and use it; or you can put a piece of copper into the fixing tray and let it remain; the silver will gradually collect upon the surface of the copper in the form of pure metallic silver, requiring only to be submitted to the action of diluted nitric acid to be converted into nitrate of silver.

Finally, by following the foregoing routine more silver can be saved than by any other means; and that the plan will work I will guarantee, as several years of constant use and practice of the same has satisfied me of its merits.

In these papers I have made it a point to suggest the simplest possible means adapted to the ends, knowing that the great mass of my brother photographers have neither the means nor inclination to adopt expensive or complicated measures. I have merely scratched out one side of a plan, to illustrate and cover a principle; and that is, a simple and inexpensive means by which you can avoid unnecessary waste of silver. And if my efforts should prove beneficial to some of my poor "shadow catching" brethren, I shall be satisfied; however, such as it is, you have it, with my best wishes.

RETOUCHING WRINKLES.

BY A. DUNBAR.

Those thoroughly versed in the various branches of the profession, my attention for the past few years has been especially directed to the retouching of negatives. This branch has been so often discussed that I feel a diffidence

CLEANING, FROSTING, AND LACQUERING BRASS.*

Taking into consideration the numerous weekly applications made to us for information on the above processes, we have thought, for the benefit of the following recipes, which will be found practical and trustworthy:

To clean tarnished brass having flat, or nearly flat, surfaces.—Make a saturated solution of oxalic acid in water. Rub briskly over the tarnished surface with a firm roll of clean flannel dipped in the acid solution. When the tarnished appearance has been removed, remove all traces of acid by swilling the article in an abundance of water. Dry quickly with a warm rag, and bring up the polish with a soft leather and a little of the finest washed whitling.

To clean surfaces which are embossed or deeply under-cut.—Make a mixture of one part nitric acid, two parts water, and six parts hydrochloric acid. Boil the articles to be cleaned in a strong soda-ley, and then leave them in the above solution until they become covered with a black layer. Now remove from the mixed acid, rinse in plenty of water, and use a fine scratch-brush to remove the black mud. When clean, rinse in hot water, and dry in hot sawdust. Articles thus treated acquire a brilliant lustre. Should it be desirable to give a very rich orange-yellow tone to the brass, the nitric acid in the last recipe may be advantageously replaced by an equivalent weight of powdered alum.

To produce a dead appearance.—This, called by the French mat, may be obtained by plunging the articles in a mixture of strong nitric acid 200 parts, sulphuric acid (sp. gr. 1.845) 100 parts, common salt 1 part, sulphate of zinc 2 parts. The articles will require thorough rinsing before the chloride of silver is applied, since the mixture contains no chloride of silver, suitable for large work.

To produce a cold appearance.—This, called by the French polissee, is made by plunging the articles in a mixture of strong nitric acid 100 parts, sulphuric acid 1 part, water 1 part, sulphate of zinc 2 parts. Dip the articles and rinse, again dip and rinse, until the earthy yellowish dulness gives way to a clear mat, without earthiness.

Frosting small brass work.—Fasten a circular scratch-brush, made of very fine brass wire, on the lathe, and having previously scorched the brass with strong pearl ash, hold the work against the revolving brush, which must be driven at a good speed.

Curling flat surfaces.—Holtsaapfel, senior, introduced this style of ornamenting flat metallic surfaces, and the following description of the modus operandi is given by his son:—"The work (after being held, scraped, and passed over with Water-of-Ayr stone) is cloaked with a piece of charcoal and water, by means of which the entire surface is covered with large curly marks, which form the ground. The curls resemble an irregular cycloid pattern, with loops of from .5 in. to 1 in. in diameter, according to the magnitude of the work. Similar, but smaller, marks are then made with a piece of snakestone, bluestone, or even a common slate pencil, filed to a blunt point. The general effect of the work much depends on the entire surface being uniformly covered; with which we shall first continue the lacquer, to prevent chilling. To lacquer a flat surface, clean carefully by boiling in American potash and water. Dip in hydrochloric acid if it be desirable to heighten the colour of the brass; wash well, first in cold water, then in hot (removing any black meadness with a fine brush), and dry in hot sawdust. When dry, burnish it required. Place upon a flat stone plate, just lukewarm. Lacquer quickly but evenly over the surface by means of a rather large but fine camel-hair brush. Be careful not to pass twice over the same spot, or a ridge is almost sure to appear. Warm the lower plate until the work is quite dry.

THE BELGIAN PHOTOGRAPHIC EXHIBITION.

Sir,—In your impression of the 19th February last you have been good enough to refer to the principal points...
April 2, 1875.] THE PHOTOGRAPHIC NEWS.

167

connected with the Photographic Exhibition to be held in Brussels in July next.

We have to thank you for this notice, and we sincerely hope that it will call attention to the matter in England, where photography has so many distinguished masters in all departments of the art.

There is, however, one observation that we desire to make. In the last paragraph of your article it is stated, "There will be no sale of the photographs exhibited." If the impression conveyed by this remark is that the exhibitors cannot sell their pictures, then it is erroneous, for all works exhibited may be sold. We shall, indeed, exert ourselves to the utmost to dispose of the articles on the most eligible terms, and to this end we have desired exhibitors to mention the price at which the pictures may be sold. (See Art. 8 of the Prospectus.) The price must not, however, be set upon the pictures themselves, and this is the only restriction imposed upon exhibitors.

May we venture to hope, in the interest of our future exhibition, that you will be good enough to make the little correction we have indicated in the next impression of your journal?

With the assurance of our profound respect,

The President—Dr. VLYDER.
The Secretary—LEONCE ROMMELLAERE.

PICTURES FOR THE MAGIC LANTERN.

Dear Sir,—Since writing my last contribution I have read with much pleasure the interesting account by Mr. Biggs of the various photographic operations by means of which a picture can be produced for the purposes of the magic lantern, but I fear he is too sanguine in supposing that to obtain an outline is an easy matter, unless he infers that no one would attempt in any way to produce a picture for the lantern unless he possessed some general artistic knowledge, both as a draughtsman and a colourist. That this must be the case is evident, as gouty and feeble lines, when so highly magnified as they appear on the screen, would (especially in architectural subjects, the rigging of vessels, &c.) become so obvious as to spoil the whole effect, however well the picture may have been coloured. As a knowledge of the various means of obtaining an outline, either of the same or of a reduced size, from a copy may be serviceable to your readers, not only for the production of lantern pictures, but also for various other purposes, I will, with your leave, offer them some information as to the various means of producing it. The advent of photography has rendered the use of some mechanical contrivances for this purpose obsolete, such as the camera-lucida. The pentapod is still, no doubt, useful, especially to architects, but its cost would prevent its being used by any other than professional men. Reticulum, or the process of producing an enlarged or diminished copy of an outline from the original, is frequently used by artists to place a design of a picture upon canvas after having first produced it as a drawing on a smaller scale; but as this requires some knowledge of geometrical proportion and correct drawing, it would prove too difficult for general use. The camera, originally constructed, and as may be now obtained at toy warehouses, offers a simple and effective means of obtaining a reduced copy of anything. The ground glass or diaphragm should be so arranged as to allow of its being removed, and thus, after the outline is made upon it by means of a blacklead pencil, it may be treated as a photographic transparency, and copied by any required size by means of photography. Although a back of the diaphragm might be desirable to a photographer, yet this would not be desirable, as the whole thing complete can be purchased at a less expense as a toy, than its materials only would cost separately. It might be as well, perhaps, to use a better lens than those generally sold with it. Then, again, it is necessary to say that the drawing of the tracing should be made with a firm and free hand. The draughtsman should understand what constitutes an outline, otherwise his labour may be greatly increased to no purpose. The most simple—and, I believe, the most effective—method of obtaining a copy of a tracing made with ink, is to place a piece of cloth or flannel, a roller now being passed over the whole, taking care that the paper above has not been shifted, a correct reversed transcript of the drawing will be found upon it. Yours truly,

JAMES MARTIN.

5, Clarence Place, Ifracones, March 30th.

PS.—Can any of your correspondents inform me of any substance that will greatly increase in size when wetted?

Talk in the Studio.

Fire at Mr. Trench's Warehouse.—A fire broke out in the photographic warehouse of Mr. Trench, in Fleet Street, on the evening of Saturday last, and continued some time before it was discovered. The damage was very extensive, some portions of the instrumentality of the firm being destroyed. The cause is involved in mystery, as the premises had been closed two days at the time the fire was discovered. Fortunately the manufacturing department was not injured, nor any damage to prevent the ordinary transaction of business.

Forbidden Portraits.—It is stated in a daily contemporary that several prosecutions of Bonapartists for the unauthorized hawkwing of books and prints have recently taken place in France. In Paris a publisher has been fined 600 francs for circulating photographs of a Bonapartist agent. In the department of the Orne a curé has been fined fifty francs for distributing pamphlets and portraits of the Prince Imperial picking up ballasts at Saarbrück; and an agent of the Bonapartist paper, the Oner, has been fined 600 francs for distributing photographs from Chielhau.

Reducing Intensity of Negatives.—Mr. R. Benecke gives the following in our Philadelphia contemporary as a sure and reliable process to reduce the intensity in over-intense negatives without in the least lessening in the faintest degree the shadows:—"I always have been an advocate of intensifying, for the reason that there was no practical way known of reducing the intensity in the high-lights without injuring more or less the detail in the shadows, or risking the negatives. I am now not more afraid to get a negative too intense than I was formerly to get it too weak. The enclosed two negatives were taken on one plate, both developed simultaneously, had the same intensity; then the plate was cut, and one half treated in the manner presently to be described. The object was a book resting on a green leather chair, and having a piece of black velvet by its side. The process is based upon the property of sulphide of silver, which combination is a very permanent or obtinate substance in regard to the action of nitric acid or cyanide of potassium, &c. Here it is. Take a very diluted solution of sulphide of silver (about one in the fixed and washed negative; watch it from the glass side. The sulphuret will penetrate the thin deposit first, and the sulphide of silver, being of a darker colour than the reduced metallic silver, the negative will look somewhat like a positive from the glass side. Now wash and dry on a solution of mercury and iodide of potassium (my favourite intensifier), or mercury alone, or iodine and iodide of potassium. The negative will now be very intense, but never mind; dip it into your cyanide bath for thirty to sixty seconds, wash it, and examine it. Should it be not quite weak enough, or did you wish some parts of it particularly reduced—as, for instance, a white dress, &c.—you may treat it again with mercury, especially those parts
S. S. Young.—Sulphate of copper is meant, we believe, in the American recipe to which you refer.

A. J. Miller.—The transparency described seems to be a piece of fast printing solar negative. No patent on it!

Conversion of Lithographic into Letterpress Plates.—A perfectly engrossed and polished zinc plate is first coated with weak phosphoric acid, then well wiped off, quickly placed over an alcohol flame, and rubbed dry with a woolen cloth. An impression on paper from the lithographic original in a moist condition is placed upon the zinc, and passed through the press. The result is then treated as an ordinary lithographic stone, except that varnish is employed instead of oil of turpentine. The plate is next wiped off and dried, and the drawing dusted with finely powdered colophon, every particle of the latter being carefully removed from the free portions of the plate. It is then very cautiously heated to the fusion of colophon, and graphite dusted upon the plate and rubbed until the drawing acquires a decided lustre. The plate is then placed in a half-saturated solution of sulphate of copper until a black deposit forms upon it, after which it is removed, washed, and replaced in the copper solution, the process being repeated two or three times, when the deposit appears in decided relief. The free portions of the plate are then coated with a mixture of gum-arabic, ocher, whitelead, &c., but not higher than the relief of the drawing, and this finally treated with a solution of gum arabic, &c., rolled with transfer ink. The drawing may be further strengthened by removing the layer of gum, immersing it in water, and treating it again with sulphate of copper, until the broad spaces are deep enough to allow it to be used in the letterpress method.

Negative Varnish.—Mr. H. L. Bingham gives the following in the Western Photographic News:—"Select four ounces of bright, clear orange shellac, rejecting any having black scales. Dissolve the shellac in twenty ounces of alcohol, and four inches high. Pour this into the prepared plate, and air dry, in a mortar, then add to alcohol, and shake thoroughly, placing the bottle in a water bath, and agitating it frequently. The shellac will soon dissolve. When cold, filter. Having powdered two ounces picked gum sandarac, add the same, and dissolve by all of water bath as before. After filtering it is ready for use."

To Correspondents.

John Holt.—We have very often described the process of fuming sensitive paper, and can only briefly indicate the method here. Take a small sized box—any kind of packing case will serve—line it with paper to make it air-tight, and see that the lid fits well. Pour a little water (say) an ounce of warm water at the bottom of the box, and ammonia at the bottom. Pin a sheet of sensitive paper with its back to the lid, close the box, and allow the surface of the paper to receive the fumes of the ammonia for ten or fifteen minutes. It is then ready for the printing frame.

A Young Photographer.—It is possible to produce enlargements with a magic lantern and paraffine lamp. A correspondent wrote some time ago describing his success. He said:—"Very good transparency enlargements in the Stereotypy style can be produced with paraffine and a good lantern. Those who wish to try this method of enlarging will find they can produce a three and a half or four inch negative in an hour. The lantern is built with iron development, with an exposure of seven or eight minutes. Pyrogallic development may be used, but the exposure may be calculated at one and a half as long. The lantern is fitted with a large half-reflector, used in connection with a quarter-plate lens. The lamp I use is known as a passage lamp, having a wick seven-eighths of an inch broad. There are only two points to be attended to in the use of a lamp of this description: first, the body holding the oil must be kept cool; secondly, the flame must be turned edge on, or nearly so, to the condenser, as the illumination is much better in this way. An oil lamp is, of course, not a state where he uses rock salt. It is probable that common salt will answer. 2. We do not know where the gasoline rollers may be procured. 3. Sulphate of copper is inflammable with water, but as being shaken the bath acts somewhat like coal in carrying down with it other matters which were in solution. Nitrates of baryta is soluble, and remains in solution in the bath. 4. Our correspondents should refer to our communication, the communication alludes to "Borinatto's last," as we are otherwise left in uncertainty as to his precise meaning.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

DULL WEATHER—HEALTH OF THE TRANSIT OF VENUS OBSERVERS.—THE INFLUENCE OF COLOURED LIGHT ON VEGETATION.

Dull Weather.—From all sides come complaints of dull weather. In November we expect little else; and, indeed, until January we generally do not look for much light during the twenty-four hours; but this year even bright frosty days have been extremely rare, and the sun has never thoroughly recovered the Transit of Venus. And not only in this country, but from the Continent, complaints reach us of the extraordinary dullness that has prevailed, and we all find ourselves looking for the warm summer time with the same longing almost as frozen-up Arctic explorers. What between the murky skies and east winds, we have been sorely tried during the present year, and never will green buds and April showers be more welcome than at present. No reliance whatever could be placed on the weather we have been afflicted with for the past six weeks. There was no knowing whether you could use up the batch of paper you had prepared, or not; and many an afternoon's work has been cut short by the suddenly darkening skies that have been oppressing us. The days of sunshine, so precious to photographers at this time of the year, since midwinter might be reckoned on one's fingers, and then the heavy clouds only separated for a time, and soon became a dense mass again, through which no sunbeam could pass. It was little use withdrawing your blinds and taking out your stops, for a brilliant well-lighted picture was sure not to come out of the question. What an unfortunate thing it is that one cannot bottle tropical sunshine, and import it like Apollinaris water, or other foreign produce! We should have plenty of trade for the West Coast of Africa then, and nobody would object to pay a heavy duty. We believe it has been tried once, and Dean Swift has given an account of the experiment somewhere, but we suppose the secret has since been lost. It is some consolation for us to know mean-while that we in this country are not the only people who have suffered from the freaks of the sun, but that our French and German neighbours have had also reason to complain, for, as we were recently told by a German correspondent, the Fatherland had been favoured this year with a total eclipse of the sun of some months' duration.

The Health of the Transit of Venus Observers.—The Transit of Venus observers, unfortunately, have not escaped the vicissitudes of travel and climate in the performance of their duties, and it is not until the end of this month that the last of the scientific staff will find themselves home again. Captain Abney did not get back soon enough to escape a slight touch of fever, while some of the New Zealand and Kerguelen's Land observing parties suffered a good deal from climatic influences. Lord Lindsay, who went to the Mauritius, might have been home a couple of months ago, but the attack of fever has so wasted him already somewhat that gaunt frame, that he was ordered to remain in Italy until the Spring. He had anticipated being back in London soon after the opening of Parliament, for his lordship is one of the representatives of Wigan, but this was found to be simply impossible, especially with such rigorous weather as we have lately experienced. The Kerguelen's parties, who constituted the most trying journey of all to undergo, will have been absent from this country ten months, so that the imperfect little photographs that have been secured, and astronomical observations that have been made, have proved very costly matters. It is a subject, however, of sincere congratulation that all the stations have been tolerably successful, and that we have not to lament any serious accident, or death, among the many scientific men who volunteered on so perilous an enterprise.

The Influence of Coloured Light on Vegetation.—An Italian chemist, M. Macagno, has, we see, made some interesting experiments upon the influence of different coloured light upon vegetation. The plants he practised upon were French beans, which were sown in boxes and allowed to grow some under ordinary light, and some under red light, yellow light, and light, the plants in the three latter cases being covered with glass of the respective colours. The seeds were sown on the 30th July, and the experiments terminated on the 24th August, taking place, therefore, in a summer temperature. It appears that of the seed sown, the last to germinate, and the first to rise, was that under red glass; in the case of the plants under the red and yellow glass, they had so changed that it was with difficulty only that they could be recognised at all as bean plants. The plant grown under white glass was far more perfect than that under violet glass, and was, indeed, the only one that came to perfection. M. Macagno examined the plants chemically, and found that the most organic matter, and also the most ash, was given by the beam of white light, and from this he concludes that all the elements of white light, and not only the actinic rays, have to do with the growth of vegetation.

ON THE EMPLOYMENT OF CHROMIUM SALTS AND PERMANGANATE OF POTASH IN PHOTOGRAPHY.

BY M. CHARDOX.*

I have thought it would be interesting to the Society to make known the results of some new experiments which I have recently made, and which, if they have not much practical bearing at present, are not without some value, and may possibly find application at some future time. The action of permanganate of potash being well defined, and conforming to theory on every point, it was easy to make experiments with copies of a similar character. We knew that if the action of gelatine upon chromic acid is prolonged for some instances, the latter is decomposed, and oxide of chromium is formed. This oxide plays in intensifying the same role as oxide of magnesium, but it has a less free action, and is therefore of less practical value. Nevertheless, oxide of chromium being a little more soluble than oxide of manganese, it may be replaced by chloride of gold, and consequently form a toning which softens down a hard image.

On repeating these experiments, and employing as original matter a film of bichromated albumen, I was enabled to confirm an assertion which has already been made, viz., that, under certain conditions, over-exposure reverses the ordinary result. Thus, having exposed to light two plates under a negative, the one for ten minutes, and the other for three-quarters of an hour, the first I found developed with regularity, and, after being intensified with permanganate of potash, yielded a positive; the second, after hand, development, and intensified under the same conditions, gave a negative.

Both plates, it must be remembered, were prepared without admixture of colouring matter. At first sight this fact appears strange, but it is easily explained. The over-exposure in the case of the second plate completely decomposed the albumen where the light had acted strongly—that is, in the transparent portions of the negative; and that the organic matter, being, as we speak, absorbed, was incapable of acting upon the permanganate of potash; whereas in the less transparent parts of the negative, the albumen, not being altogether decomposed, had been capable of precipitating the permanganate in proportion to the tints of the cliché. For this reason a negative is produced by means of a negative.

* Bulletin de la Société Française,
permanganate of potash may be in photography. In a process based upon its use to which I recently called attention, I proposed to employ it for intensifying carbon transparencies on glass, so that they might be used as negatives; and one of my colleagues has now claimed the honour of having discovered and patented this circumstance as far back as last October. Without in any way questioning the value of this patent, such a subject being out of the province of this Society, I will discuss from a theoretical view the formula given in this communication. The patent is thus worded:—

"The gradual intensifying action which I apply to the chromic salts is a solution of 300 cubic centimetres of water, 10 grams of permanganate, and further, according to the vigour of the cléche desired, a few drops of a saturated solution of permanganate of potash. The cléche is put into a bath containing this solution, and then, if one desires more intensity, the liquid is strengthened with a little more of the permanganate solution. The cléche thus intensified gives a print of the same depth as the original. I claim, therefore, this mode of intensifying cléches, also new methods of using chromic salts, &c.

The patentee has given little attention to the theory of the matter, for he intensifies by means of chromic salts, and these salts are without action upon permanganate of potash. He forgets one point which is to make clear the question, for he does not indicate that the reaction operates upon organic matters, such as gelatine, gum, sugar, albumen, and other bodies that might be utilised in photography. Let us pass to the solution: water 300 cubic centimetres; one drop of ammonia, which is absolutely useless unless it is to soften the organic matter, of which no mention is made; sugar one gramme. Here, theory seems to me at fault. Either the sugar is in too small a proportion in the solution, and then it is valueless; or, if its proportion is large, it is injurious, for in that case it reduces the permanganate and other intensifying action, the latter not taking place, it must be remembered, in the same way as if salts of silver were employed. In the latter case the intensifying solution is generally composed of pyrogallic acid, nitrate of silver, and acetic acid, to retard the formation of gallic of silver. It acts by a decomposition of the solution to the advantage of the image, a proportional decrease of the colour.

Intensifying by means of permanganate of potash takes place in a different way. It is decomposed only in such places where it is in contact with organic matter, and the proof of this is that the permanganate which is not decomposed leaves a solution perfectly limpid, which may be employed in a subsequent operation. It is necessary, therefore, to suppress in the solution all organic matter which will be liable to decompose without advantage to the image.

In suggesting the employment of pure and simple permanganate of potash, I have said that with gelatine alone perfect images may be obtained; I may add that this is the case with all organic matter susceptible of being spread in uniform films.

If only knew the process which has been taken as the basis of the patent of my honourable colleague, I should be in a position to reply to the observations he has made in his usual courteous manner. I may add, in conclusion, that I had no pretence to the invention of permanganate of potash, nor to its applications, but I cannot accord this honour to the owner of the invention patented in October 1874; for already in 1868 I find in the Bulletin a communication by Mr. Wharton Simpson, who, in some highly interesting and perfect original researches, indicated an application of this product which he used for the purpose of intensifying cléches produced by means of silver salts. Furthermore, in a communication made by Mr. Swain, in 1872, which is now before me, I find that gentleman, whose works upon carbon printing are well known, has indicated the employment of permanganate of potash for the progressive intensifying of carbon impressions. He indicates the care which it is necessary to employ in making use of the process, the reaction produced, and the formation in the film of gelatine of sesquioxide of manganese. He gives details relative to transparent positives, as also to colouring by the action of permanganate of potash; he omits none of the practical details, and supports everything upon his theory. These facts I leave for the consideration of all.

THE PRACTICAL PRINTER IN AMERICA.

"CITRIC ACID TONING BATH.

'This is a most excellent bath, either for portraits or landscapes, there being, at its composition no strong alkaline or acids that will be apt to hurt the albumen on the prints a particle. We used this bath two years, and it is a most worthy one. Here it is:

Solution No. 1.

Citrlic acid... ... ... ... 1 ounce
Water ... ... ... ... 20 ounces

Solution No. 2.

Chloride of gold... ... ... ... 15 grains
Water ... ... ... ... 15 ounces

Stock Solution.

Now take of Solution No. 1, 21/2 ounces; make slightly alkaline with saturated solution of bicarbonate of soda 21/2 ounces, or about that. Solution No. 2, 1/2 ounce; water, 65 ounces.

"When ready to tone, take sufficient of the stock solution (which should never be less than three or four days old) and add thereto one ounce of gold solution No. 2, and make this fresh solution which you are about to add to the bath a little alkaline with bicarbonate of soda.

"A better way, however, for the beginner to add this fresh gold to the bath, instead of pouring the gold immediately into the bath, is to pour it first into a clean graduate, and there make it alkaline. Pour some of the toning solution (stock) into the graduate, and thoroughly stir with a glass rod, and then add the whole to the rest of the bath which is in the dish, and stir well again. To every four sheets of paper you tone, add about an ounce of gold solution; adding, however, at different stages of the toning operations, and not all at one time, as that would make the few first batches of prints tone too rapidly. Do not add any gold while there are any prints in the bath, and stir well, and allow the bath to stand without being used for about three or four minutes after you add the gold. I recommend the above cure to beginners, because they often obtain uneven tones by the abuse of the advice given above.

"Do not tone in a too strong light, but in rather a weak one, and judge not tone of the prints while in the hand, but while lying down in the dish.

"Tone exactly as you wish them when dried, and no more nor less. Wash the prints constantly in running water after toning. Fix as usual.

"BICARBONATE OF SODA BATH.

"This is probably one of the best of baths, and I have seen some of the very best of tones obtained with it.

"It is argued by some that the simpler a bath is the better, and that it is only chloride of gold in the toning bath that tones, and that all other ingredients that are placed in the bath are useless; and this bath is just what these photographers advise, since there is nothing else to be placed in it. Here it is:—

Chloride of gold solution (one grain to the ounce of water) ... ... ... 1 ounce
Water ... ... ... ... 16 ounces
Bicarbonate of soda (saturated solution) ... ... ... ... 10 minims

Make half an hour before use, so as to allow it to ripe.
examine them, for you will surely then be deceived, and take them to be under-toned, when by examining them lying in the dish they will appear to be toned plenty.

"The prints are toned when the high-lights and half-tints of the face appear clear and a little blue when they are lying down in the dish and examined in a weak light. Take them out immediately, even if upon looking at them in a stronger light the shadows and draperies should appear as red as fire, for the prints are toned. In nine cases out of ten you will at first overtone the prints rather than undertone them. Tone for the lights and half-tints, and let the shadows take care of themselves.

"The salt in the above bath is the improvement of this bath over the common sal soda bath, and it is partly owing to this salt that such beautiful tones can be obtained. In case you overtone, the tone will never be a disagreeable slaty one, but rather a pretty blue."

THE SULPHUR FLAME AND OTHER LIGHTS SUITABLE FOR PHOTOGRAPHY.

BY MM. A. RICHET ET C. BARDY.*

MM. DELACHANAL ET MERMET have published a very interesting note, in which they give a description of the bisulphide of carbon and binoxide of nitrogen lamp, which produces in a continuous manner a very photogenic light, such as till now has been obtained but in an intermittent manner, and for a few instants only. The apparatus consists essentially of a glass flask containing bisulphide of carbon which is directed a current of binoxide of nitrogen, and of a metal tube filled with iron filings to prevent explosions, at the extremity of which the mixture is inflamed.

This question of artificial illumination is one of much interest, because the production of photographic enlargements is often conducted by means of artificial lights; moreover, it is by their aid that night scenes are reproduced, and dark localities are illuminated. In countries, too, where sunshine is more rare than in ours, the use of artificial light is a matter of greater importance, and no wonder the English journals have interested themselves in the matter, and special mention has been made of the dangers of explosions, which such an apparatus as that just described may be liable to.

In considering our experiment, which have also struck us, have led us to examine the subject once again, and to seek means of guarding against dangers that may arise, either by modifying the method of operating, or by suppressing the employment of the bisulphide of carbon altogether; we also determined to examine and compare the nature of various flames which are capable of impressing the salts of silver.

1.—We started with the natural idea that the flame of bisulphide of carbon and binoxide does not owe its photogenic power to the carbon, that burns with a yellowish white flame, but to the sulphur, the light of which is of a very pure blue. To realise this idea we fused some sulphur in an earthen vessel, five centimètres in diameter, and, when liquid, we directed by means of a tapering tube, placed as vertical as possible, a jet of oxygen coming from a gasometer. In this way we produced a continuous blue flame, which quickly impressed bromide of silver, as will be seen in the table of results given below.

If nitrate of potash is heated in the same manner to a temperature at which it begins to decompose, and fragments of sulphur are thrown into it, the light is very bright, white, and endowed with less photogenic activity than the preceding light.

2.—We substituted in the second experiment bisulphide of carbon for the sulphur, directing the jet of oxygen upon the sulphur alight in the vessel. This liquid burnt

* Bulletin de la Société Française.
without explosion, with a blue light, similar to the preceding one.

3.—We replaced, in a third experiment, the oxygen by binoxide of nitrogen, the operation being conducted as in the former experiments. The gas was in the same gasometer which previously contained the oxygen, and the table and vessel were the same. The light appeared similar to the previous ones, but, as will be seen further on, its photogenic power was less.

It is evident that no explosion need be feared when the bispurphide of carbon is operated with in this manner, because the reacting bodies are not enclosed in an apparatus of oxygen, and hence the binoxide of nitrogen upon the sulphur on the surface of a bath largely mixed with air.

The importance of substituting oxygen for binoxide of nitrogen is at once apparent, whether regarded, on the one hand, because the gas is more easy to prepare and more economical, or, on the other, because it does not give off any gases dangerous to breathe.

4.—We next proposed the comparison as closely as possible of the foregoing lights obtained without risk of explosion, with a light given by means of a current of oxygen or binoxide of nitrogen upon bispurphide of carbon enclosed in a flask.

The gas, after having traversed a bottle filled with pure water, was introduced with bispurphide of carbon which was passed through a long tube of glass containing iron filings and was then illuminated at the extremity of a metal tube of a larger caliber than that used in the preceding experiment, through which the oxygen or binoxide was generated. With the oxygen we took the precaution of surrounding the flask and the tube with carpet, a precaution which was not altogether futile, for as soon as fire was approached, the flag on the apparatus, which burst, and the bispurphide of carbon took fire.

The experiment succeeded perfectly with the binoxide of nitrogen and the bispurphide of carbon, and the bispurphide of silver was vividly impressed, but with an intensity less great than was the case with the combustion of sulphur in oxygen. At the same time, we may remark that this experiment cannot be compared to the preceding ones, in the same way as these may be likened to one another, because the form of the flames is different, and the gaseous mixture has been checked by the iron filings and pumice stone, an effect that we have desired to counterbalance by augmenting the caliber of the delivery tube.

Finally, we have compared the sulphur and bispurphide of carbon flames, to the oxyhydrogen light obtained by carburetting ordinary coal gas with petroleum spirit, with the Drummond light, the magnesium, and that given by zinc strongly heated in a jet of oxygen. To appreciate the chemical activity of these lights we exposed to their action, under identical conditions, some sensitive dry plates produced by the excellent method of M. Slebbing, who was good enough to prepare for us a large plate, which was cut into stripes two centimetres broad by ten long. The experiments, of which the results are given in the table below, were all made the same evening. The sensitive plates were fifty centimetres from the source of light, and the exposure lasted sixty seconds, the time being measured by means of a chronometer. The sensitive plates were enclosed in a frame under a cover formed of ten sheets of waxed paper superposed, two centimetres broad, and of variable length. One measured ten centimetres, and consequently covered exactly the whole of the sensitive plate; the second measured nine, the third eight, and so on, so that the last sheet was but a centimetre long. These sheets were pressed between a layer of glass on one side, and a layer of horn on the other, and there were figures from a to ten at equal distances, so placed that No. 1 corresponded to one sheet, and No. 10 to the ten sheets superposed. In this way a screen was obtained the opacity of which was proportional to the number of sheets superposed, and which were indicated by numbers. If, for instance, it was seen that after an experiment the figures 1 and 2 were printed, and in another 1, 2, 3, 4, 5, it was obvious that the photogenic power of the second light was to the first as 6 is to 2. All the plates were developed together, and every experiment was repeated. The following table enumerates the principal results obtained:

It is therefore the light obtained by the action of oxygen upon sulphur which appeared to be endowed with the greatest amount of chemical activity upon bispurphide of silver, and we do not hesitate to recommend a practical trial of this illuminating method. There is no danger of explosion to be feared. It is, moreover, far from costly, for the only things wanted are a saucer or crucible for the sulphur, and a bag of oxygen, a gas that anybody can make for himself, or can purchase if he prefers it.

By replacing the earthen crucible by a vase of an elongated shape, into which are directed five jets of oxygen, we obtained, as may be imagined, a much more active light, and which, on an apparatus of higher seconds, rendered the figure 9 apparent on the sensitive plate.

By replacing oxygen by atmospheric air under great pressure, a blue and faintly luminous flame was obtained, possessing but very little photogenic power.

A mixture of oxygen and air gives a light whose action upon salts of silver is in direct proportion to the amount of oxygen it contains.

Finally, by substituting the protoxide of nitrogen for the oxygen, we obtained a very beautiful blue flame, whose photogenic power is about one-fifth less strong than that of the flame produced by a current of oxygen when operating under the same conditions.

Protoxide of nitrogen may be prepared with the utmost safety, by means of an apparatus and flame which are without danger in India-rubber bags; we think that it may be substituted with advantage for oxygen, the price of which, if obtained by means of chlorate of potash, is much higher.

The process has a drawback in common with all the bispurphides of carbon methods, viz., the suffocating smell of the sulphurous gas that is formed. This inconvenience is easily remedied in a laboratory where a cupboard or chimney can be made use of, or may be put up with in a spacious apartment, but in a small room the matter becomes serious. It may be obviated by placing a funnel above the vase communicating with the chimney by means of a tube, a current through which is established by means of a gas flame, or better still by placing the whole apparatus in a glass cupboard communicating with a chimney.

In a studio the extremity of the funnel may be put in communication with an aspirator, forcing the products of combustion to pass through a series of Woelfl bottles containing an alkaline solution, which effectively absorbs the sulphurous acid.

The apparatus we have described is only a rough one, for we have confined ourselves merely to the production of light; it can be improved by a much safer and more powerful, and perfectly free from danger, leaving to each experimenter the question of constructing his apparatus in the most appropriate manner.
In conclusion, we beg to call attention to another light whose employment we believe would be of great service under many circumstances. Everybody uses in their dark rooms yellow glass and yellow light, which is unfortunately not always free from action upon silver salts. By replacing this with white light, and the aid of this glass with the monochromatic sodium flame, one may operate without the risk of fogging the most sensitive compounds. This circumstance we have proved by placing a bromide of silver plate, half covered with an opaque shield, at a distance of ten centimetres only from the flame, and heating it in this manner for five minutes. After development both halves of the plate were precisely the same, and no trace of fog was perceptible upon the half that had been exposed.

This sodium light may be obtained by burning ordinary gas in a Bunsen jet. The Bunsen burner employed in all laboratories is constructed in such a way that the gas, more suitable proportions, burns with a scarcely visible blue flame; and in this way it is heated. Two-thirds up this flame is introduced a little wick formed with platinum gauze, and containing a grain of marine salt, fused, about the size of a pea. The flame instantly assumes a yellowish tint, becomes very brilliant, and continues so long as there is any salt left on the little wick. The only precaution to be taken is to place from time to time a little fragment of salt upon the gauze whenever the flame grows less brilliant.

TOUGHENED GLASS.

The following interesting details in relation to the production of a glass much less fragile than that in use, to the discovery of which we recently referred, appear in the Times, and will doubtless interest our readers:—

Although the manufacture of glass has been carried on for about two thousand years, it does not appear that any attempts to overcome its inherent brittleness and liability to fracture, and at the same time to preserve its transparency, have proved successful—if, indeed, they have been made at all. Which is not difficult, and not that the French philosopher Reaumur many years since hardened glass somewhat by exposing it to a high temperature for a considerable time. But this process, which is technically termed devitrification, while it hardens, at the same time destroys the glass. It renders it opaque, the product being known as Reaumur’s porcelain. Seven years since, however, M. Francois de la Bastie, a French engineer, began to investigate glass, and was thus led through the most difficult channel of research to the discovery of a simple means of rendering glass practically unbrittle, and at the same time of preserving its transparency. There were many delicate conditions involved in the process by which he obtained this result, his success being achieved much in the same way as was Pailley’s, but on endeavouring to repeat the successful experiment he failed signally. For two years more M. de la Bastie, who possesses ample means, tried in vain to rediscover the secret of his success. At length, however, he succeeded in doing so, and has since been engaged in perfecting his invention, and in developing a laboratory experiment into practical working. The process of conversion of the main body of its simplicity, that it seemed singular it was never thought of before. Broadly stated, it consists in heating the glass to a certain temperature, and plunging it while hot into a bath composed of a half-saturated solution, by which it is covered a simple means of rendering glass practically unbrittle, and at the same time of preserving its transparency. There were many delicate conditions involved, and the details of the process upon which a satisfactory result depends, and the neglect of any, even in a slight degree, constitutes the difference between success and failure. The view of solving this problem, by the effect of the bath, or it may be overheated, and it will then lose its shape, or, again, it may be slightly heated and yet be spelt in the course of transformation to the bath. Moreover, this same condition continues until the glass, temperature have an important bearing upon the ultimate result. These and numerous other points of detail have all been satisfactorily settled by M. la Bastie, who has designed a method of which his toughening process can be carried out practically without fear of mishance. The time occupied in the actual process of tempering is merely nominal, for directly the articles are brought to the required temperature they are plunged into the bath and instantly withdrawn. The cost of tempering, too, is stated to be very small.

We have observed that M. de la Bastie went through a long course of experimental research before he attained success. He first worked, as an engineer naturally would, upon mechanical principles. Knowing that the fragility of glass results from the weak lateral cohesion of its grains, he was impressed with the idea that, by forcing those molecules more closely together, and thus rendering the mass more compact, the strength and solidity of the glass would be increased. But this, it must be remembered, is a very different thing from solidifying the glass with iron and steel, as Sir Joseph Whitworth has practically demonstrated, does not apply to glass: compression failing to toughen it, even if applied to it when in a fluid or soft condition. By applying compression to glass, which is cut, and in which a wire is introduced, is attained, and the physical properties of the material become altered in a very remarkable manner. To this singular fact we can testify from the inspection of a number of toughened glass articles, at the office of Messrs. Abel Rey and Brothers, 29, Minning Lane, the representatives of M. de la Bastie in England. In those articles, which consisted of watch cases, plates, dishes, and shot glasses, both coloured and plain, neither transparencity nor colour is affected at all, and the ring or sound only slightly. These articles—some of them being exceedingly thin—were thrown indiscriminately across room against wall and fell spinning on the deal floor. Water was boiled in a sauce over a fire and the saucepan was knocked out and removed to a comparatively cold place, and was unaffected by the sudden change of temperature. One corner of a piece of glass was heated and expanded, and the piece was then cooled, but the heat was not communicated to the other portion of the glass, neither was it cracked from unequal expansion. A comparison of the experiment was then made with a piece of ordinary plate glass, and a piece of toughened glass, in which the respective powers of resistance to fracture, from the force of impact by a falling weight. In each case the glass was about six inches square, and was placed in a frame, the weight being dropped from a given height into the centre. With the ordinary glass, a two-ounce brass weight falling on it from a height of twelve and eighteen inches respectively did no damage, but at twenty-four inches the glass was broken into several fragments. With a similar piece of toughened glass, the same weight was dropped from the same height, the pressure was the same as before, but the two pieces, when inspected, gave similar results. Upon the height being increased to six feet, however, the glass broke. But here another singular result was produced instead of breaking into about a dozen pieces, as did the ordinary glass, it was literally smashed to atoms. The largest fragments measured about half an inch in length and breadth, and these were easily removed by the fingers to atoms varying in size from that of a pin’s point to that of a large pin’s head. The lines of fractures in the fragments presented to the eye the appearance of irregular lace work, and these lines were, moreover, apparent to the touch, but more palpably so on one side of the glass, which was the side on which the fluid was introduced. The first impact of the blow we were unable to determine. Another peculiarity is, that the edges of the fractures are by no means sharp, and therefore capable of cutting through the skin. It would seem that the toughened glass possesses enormous cohesive power, but that if the equilibrium of the mass is disturbed at any one point the disturbance or disintegration is immediately communicated to the whole piece, the atoms no longer possessing the power of cohesion.

Of the practical nature of M. de la Bastie’s unique discovery there can be no question whatever, nor can there be any doubt of its value in the arts, sciences, and manufactures. The applications which suggest themselves are innumerable, and above and beyond the usefulness of the process with regard to articles of domestic use come important considerations affecting the applied sciences, especially in connection with chymical manufactures and similar industries, where a material, alike uninfluenced by the action of heat or acids, has been so long and so vainly sought for—notably in connection with vitrol chambers in the manufacture of sulphuric acid, and for piping in chymical works. For the present there remains one purpose to which toughened glass cannot be so easily applied, and that is to water staining in odd sizes, as in the making of vases, pipes, or other ordinary means. Our glaziers will therefore have a respite, but we cannot give them much hope that it will prove a long one, as experiments of considerable promise are being conducted in this direction, and devices are being invented by experts for cutting the proper sizes before toughening if desirable. The glass, however, is readilyearable either by fluoric acid in the usual way, or by Mr. Tligmann’s elegant sand-blast process. It can be easily coloured, and it can also be treated to acquire a metallic lustre like the like. It only remains to congratulate M. de la Bastie on the useful and valuable discovery he has made, and to add that he is carrying out his works in France to carry out in practice his ingenious process.
THE NEW SIZE IN PORTRAITURE.

An interesting illustration of the wide-spread feeling amongst professional portraitists that the introduction of a new size was desirable, not only for the purpose of giving a new stimulus to trade, but to fill an existing hiatus in the ordinary series of sizes adopted in photography, is found in the fact that a new size, in some respects analogous to that suggested by Mr. Blanchard, is receiving attention in the United States. In both cases a size that largely exceeds the former, and of proportions analogous to those of the card portrait, have been adopted; but, amusingly enough, names not only different, but diametrically opposite, have been chosen. Mr. Blanchard, as our readers know, has chosen the term “Boudoir Portrait,” as suitable to the new size and style; whilst our American friends have adopted the term “Promenade Portrait,” as appropriate. The size and proportions of the Boudoir portrait, our readers know; the following are the dimensions of the “Promenade”: the mounting card is seven inches by four inches, the print is one inch and an eighth less than the card, leaving a white margin of one-sixteenth of an inch. The print itself, however, is surrounded by a fancy photographic border of a marble pattern in the example before us—somewhat less than half-an-inch broad. This leaves the print proper just twice as long as it is wide, the size being six inches by three inches.

The proportions in both cases are clearly chosen with an especial value to effective standing pictures of ladies; and it is probable that in each case a variety of good reasons may be adduced for the proportions adopted, and no change is likely to be accepted in either country. One of the best reasons, perhaps, which now exists for English photographers adopting Mr. Blanchard’s size is the fact that mounts, albums, frames, and various other adjuncts for such a size have been prepared and are accessible. Hence if the size be accepted by common consent, sitters having once tried the style, can fill their albums and obtain a profusion of prints of the kind throughout the kingdom, to the manifest benefit of all. But, apart from the argument derived from facilities prepared, we think that the proportions of the “Boudoir” portraits are best in an artistic sense. Mr. Faulkner and some others have protested against it as too “lanky,” earnestly desiring that the width should be a little greater in proportion to its height. The arguments would apply to the “Promenade” portraits also, for that form. Whilst the proportion of width to length in Mr. Blanchard’s pictures is, speaking in round numbers, as two to three, in the American picture it is but as two to four. In Mr. Faulkner’s interesting communication in our last, he gives the actual proportions of the canvases for varied styles of portraits which have acquired a classic character by universal acceptance amongst great painters. As it will be seen, they are, in the majority of cases, much wider in proportion to length than the usual sizes which have of late prevailed in photography. But this table of sizes really affords a very strong argument in favour of the proportions adopted in the “Boudoir” portrait.

As Mr. Faulkner rightly remarks, the proportions of portraits in photography may surely be safely called on the same principal adopted by great artists who have painted portraits; and it will be seen that the standing whole-length portrait of seven feet ten inches by four feet ten inches is, as nearly as it is possible to be, of the proportions adopted by Mr. Blanchard in the “Promenade” portrait, which is essentially intended for standing figures.

It is possibly a misfortune that no facility of any kind exists for intercourse and consultation between professional photographers on points interesting to the profession. If any organization existed for such a purpose, subjects like the one to which we have been referring might fittingly be considered and decided, either by the general vote, or by that of a majority, especially in the case of large portraits. A committee of counsellors there is wisdom: and, besides the probability of a satisfactory decision being obtained as to size and proportion, in such a case mutual agreement would secure common action, and all the very definite benefits which arise from universal consent in introducing a novelty to the public. Meanwhile, we heartily echo Mr. Faulkner’s demand for facilities to facilitate the shape of albums, for some other proportions better suited for half-lengths, busts, &c., than those of the card and Boudoir portraits, which are manifestly best suited to the rendering of whole-length figures. There is no better method of creating and increasing demands for portraits than their display in the proportions and with such encourage which gives them their highest pictorial value. Good taste in this respect is in many cases especially to any work, whilst bad taste may deprive the finest picture of its real value. All portraitists have, therefore, an interest in giving weight to Mr. Faulkner’s appeal to manufacturers to depart a little from the cut-and-dried groove, and furnish the desired novelties.

PHOTOGRAPHY IN THE WEST.

The tide of civilization and progress throughout the world’s history has flowed westward, and the course of photography, as one of the most interesting developments of civilization, is certainly no exception to the general law. In the early days of the art it made much more rapid strides in America than in the Old World; and, if we may judge by many of the evidences which come under our attention, the set of the tide of photographic progress is still westward, even on the American continent. The next meeting of the National Photographic Association will be held in San Francisco, the city in which the President of the Association (Mr. W. H. Rulofson) is a distinguished photographer. But amongst the cities of the Western States it is Chicago which attracts attention as a city in which photography especially progresses. It is the home of a large number of exceptionally skillful portraitists; it possesses an active and successful photographic society; and it has recently commenced the issue of a most interesting and promising photographic journal entitled the Western Photographic News, published by Mr. C. W. Stevens, proprietor of a very large and flourishing photographic deposit, and edited by Mr. G. A. Douglas, Secretary of the Society. The annual dinner of the Photographic Society, held some weeks ago, appears to have been on a very grand scale, and the proceedings singularly successful and interesting. We were fortunate enough to receive an invitation to this dinner; but, unhappily, the few thousand miles which intervened proved an insuperable obstacle to
THE PHOTOGRAPHIC NEWS.

April 9, 1875.

The pleasure we should have had in meeting the Chicago photographers. The very handsome printed ticket, and a menu including nearly a dozen courses, forwarded, enabled us, however, to form some idea of the style in which the thing was managed. A circular issued about the same time—dating, as is the fashion with another craft, anno lucis, in place of dominus—gave the varied advantages of the Society, and invites attendance at its meetings.

Photography in Chicago is a sufficiently prominent fact to demand the notice of the daily press of the district, and a number of the Chicago Tribune before us devotes nearly four columns to a very well written history of photography in Chicago, with notices of the most prominent photographers at present practising there. In Chicago, it is said, "the chief places of business and art were offered to the public in a rude, aboriginal fashion within eight years after the first publication of the discovery in France," and "the interest has since developed with a rapidity unparalleled in any other department of industry, until the business, at the present time, is represented in seventy-five galleries, giving employment to three hundred operatives, besides those engaged in stock houses and other branches of commerce connected with the art. There is probably no other city in the world," the Tribune adds, "where photography has attained a higher degree of efficiency and practical perfection, or where a higher order of intelligence, enterprise, and skill are exercised in the interest of the art, than in Chicago." A detailed notice of the studios of a number of the leading artists and followers, and of the chief places of business associated with the art. Amongst the latter, the "Great Central Depot" is described as an "extensive four-storey marble-front building," and its proprietor, Mr. Stevens, the proprietor of the journal to which we have referred, as probably "the most extensive importer, manufacturer, and dealer in the west." Our readers will probably agree with the author, "that no city does photography appear to have attained a higher position or greater vitality than in Chicago, the Garden City.

THE SOLAR ECLIPSE.

Dr. Hermann Vogel, of Berlin, our readers will remember, accepted the invitation of the Royal Society of London to take part in the Solar Eclipse Expedition, to observe the eclipse which took place last Tuesday, the 8th inst.; and our esteemed colleague has sent the following account of the observations which it is proposed to make to the Photographische Notizen:

From many sides I have had questions touching this new expedition to India addressed to me, and I cannot do better, I think, than answer them in your journal. It is a question of another solar eclipse when the sun will be completely hidden by the moon for a space of three minutes, so that only such portion of the great luminary is visible as stretches out beyond the margin of its disk (that is to say, the atmospheres surrounding the sun), and these appear to be of a most wonderful nature. In the first place, there are carmine red flame-like forms, which here and there project from the obscure orb: these are the protuberances. Then around the luminary again is a broad white halo of glory, as it were, of irregular form, which is called the corona. When, in 1868, the Eclipse Expedition went out to Aden and to India, it was one of our duties to fix the form of the protuberances by photography, and this we were enabled to do. It was found, however, that in the pictures taken at Aden, and in India an hour later, the form of the protuberances changed, and that they had no fixed shape, but altered pretty much as our clouds do. At the same time it was proved by observances made with the spectrums that the protuberances were nothing more than glowing hydrogen gas. This was not difficult to prove. If, for instance, a spectrum apparatus is directed towards a tube in which hydrogen gas is warmed to a glowing heat by the passage of electric sparks, there are to be seen in the spectrum three bright lines—a red, a light blue, and a dark blue line. When directed towards one of the protuberances of the sun, there are to be seen precisely the same three lines; therefore it is obvious that one is looking at glowing hydrogen. At the present day we have arrangements by means of which the bright lines of the protuberances may also be seen in full daylight without an eclipse, and it has been seen how these strange forms appear and disappear rapidly, as if they were mighty explosions of gas upon the surface of the sun. They are not problems to us any longer, and in the more recent solar eclipses we have therefore directed our attention more especially to the halo of light, or corona, of the sun.

In America, in 1869, an attempt was made, and successfully, to photograph the corona. The protuberances are brighter, and impress the plate more quickly, five seconds' exposure being enough for even a weak lens. Much less vigorous is the light from the corona, for in this case eight times the exposure is necessary. In such a picture as this the protuberances appear over-exposed, but the corona appears fully. That the camera is constructed in the form of a tube, and not in the ordinary box shape, is a matter of importance in so far as photography is concerned. The camera should be connected with a clockwork arrangement to move the camera at the same rate that the sun—or, rather, the earth—is moving, is of the highest importance. A great deal depends upon the care with which this movement is controlled, for if the camera does not quite follow the course of the sun, an unsharp image is the result.

In this way both corona and protuberances have been photographed, but in the former case the pictures have taught us little. Here again the spectroscope came in to solve the problem. Different bright lines were to be seen on examination of the corona, which were different from those furnished by the protuberances, and the nature of these lines we have yet to learn. For this reason it is that we are making frequent and rapid measurements of the solar eclipse, in the hope of clearing up the matter. As, however, the eclipse only lasts a short time, and during the brief period at the observer's disposal many things may be overlooked, photography is now to stop in and aid in the spectrum observations. This time we are going to try to photograph the lines so that these may be studied afterwards at leisure. We shall take from an exposure of five minutes at the camera, and from a glass plate with the cameras alone we can do nothing. A spectroscope is necessary in combination with camera or telescope, and the photographic plate lies behind this. Description of the apparatus would lead me too far, but I may briefly say that first comes a telescope, then the stereoscopic, and then the photographic apparatus, all three on a stand, which is moved by clock-work.

The photographic work is carried out by means of ordinary collodion of the most sensitive possible character. No impression is made by the yellow and green lines, but the violet and blue are well reproduced, and it is just these which are difficult to see with the human eye. I shall, however, try to reproduce the former with my prepared bromide plates, which, it is well-known, are sensitive to the green and yellow portions of the spectrum. The difficulty to be overcome is the circumstance that in spectr um photography but very little light enters the camera, and, consequently, a very much longer exposure is necessary than in the case of depicting corona.

The eclipse at which this interesting experiment will be made lasts three minutes. The exposure of the plate cannot last longer than this, therefore, and we must hope that it will suffice. There are other difficulties, such as those connected with a hot climate, &c., but if there is a supply of ice handy these should be overcome without much ado. A great deal, of course, depends upon the nature of the apparatus, and the quality of the telescope employed.
The Royal Society of London, which has organized this expedition, invited three foreign savans to take part in it—a Frenchman, an Italian, and a German. Responding to the call, I am now on my way to the field of operations, this being the third Solar Eclipse Expedition that I have undertaken. The party go together to Ceylon, and then we divide; one portion goes to Siam, one to the kingdom of Birman, and one to the Nicobar Islands. I am going to Birmah. Besides myself, there are other photographers, whose task will be, however, but the depiction of the corona. It is only with the photographing of the spectrum that I have to do, and it is hoped that the aid of some of the members of returning Transit of Venus parties may be pressed into the service. Several gentlemen have, in fact, arrived at Calcutta, where I join them to make the journey to Birmah.

The eclipse takes place on the 6th April, and after that I propose going on to India to undertake some experiments relative to the intensity of light in that country. After my experiences I will relate further in another letter.

SEASONABLE THOUGHTS SHOT AT RANDOM.

BY W. T. HAMB.

Although the respective operations connected with silver printing have been exhaustively dwelt upon by writers innumerable, and theorists have vied with professional practitioners in making all things connected therewith clear to less gifted inquirers, yet, somehow, an important matter belonging to the process, known as toning, has been overlooked, and it is with the omitted information alluded to I purpose now to deal.

For years past I have never ceased to warn photographers against that rigorous truthfulness they are but too prone to place in formule; and I have from time to time endeavoured to show how evils complained of might be averted if printers could only be persuaded to make their work a trifle less mechanical. That a foolish reliance on the virtues embodied in so many ounces, grains, or drachmas, is, as a rule, the way to failure, I have proved a thousand times in my earlier experience. That success depends on an intelligent guiding hand is now my desire to show.

"Beautiful Spring" brings with it something more than plum blossoms and primroses; for with these pleasant months the photographer associates his often longest-after time when the air is charged with plenty of action. March, April. May, contain red-letter days, more especially for the printer, who, without experiencing the exhausting heat of later months, can go the whole frame, and find in each the very best impressions the negatives are capable of producing; and if he has any but a sluggish, unsatisfactory nature, his whole soul glows with pleasing anticipation of a glorious crop of prints to place before his employer on the coming morrow. With extra care he trims and washes his prints, the required preliminaries which precede the toning. He mixes his gold solution, as per written rule, places it in a well-washed dish, immerses the prints, and then he is in spirit-damping troubles. The pictures come so extraordinarily fast his nimble fingers cannot keep the color within desired limits; and, what makes the matter worst of all, there is no fugitive colour to be removed by the hypo. Ultimate result: inksiness, absence of richness, even though there be no loss of vigour. Now the reason why disasters such as just described are no means difficult to discover. Spring time presents all the requisites for extra perfect printing. The air is cool and moist, the chemical rays are at their maximum vigour. Under such favourable conditions the prints produced possess enlarged magnetic attraction, and in that state need a very weak gold solution to tone them; otherwise, if the ordinary strength is given, the gold is hastily decomposed, and certain black spots follow. In my own case, a day or two after for the past week I had been adding to my toning bath from two to three grains of gold daily, and have found that quite enough to tone over a

quire of paper; i.e., I give the gold fair play, be it remembered, not bothering it with haloid adjuncts, acetates, carbonates, and so on. Very wrong in me, doubtless, thus to bid defiance to popular opinion. Fact of the matter is, I succeed, and cannot, for that reason, afford to part with eccentricity. To those who at this time are troubled with the effect already first found so nicely, but now yields colour of ink, I tender this advice: reduce materially the strength of your toning solutions; and for guidance I once more repeat: a print, to be brilliant, must have merely a transparent glaze of gold, for if the red beneath is killed by too opaque a covering, blackness results, and adieu to translucent tints of ravishing richness.

FUMING WITH AMMONIA.

Appropos of this subject, I am sorely puzzled when I notice among the queries addressed to Mr. Editor an inquiry whether fuming with ammonia makes any difference in the quality of the prints. Surely the best answer to such questions would arise from actual trial. I practised this system several months, and am thus enabled to say that under certain conditions there must be placed to the credit of fuming an important amount of advantage, more particularly with low salted papers, or where nitric acid has been sparingly mixed (a most pernicious practice) with the albumen to make it more readily workable. In establishments where a considerable quantity of paper is used every day, however, the process of fuming consumes too much time; and for that reason I have taken some pains to obtain the advantages that arise from the practice without the trouble of submitting the sheets to the ammonia exhales, and after many trials discovered that with a judicious admixture of chloro-ammonia with a slight salt of ammonia fuming might be dispensed with; at all events, as far as my own work is concerned. Some photographers, believing that an addition of ammonia to the silver bath would serve in lieu of fuming, have tried it, and the experiments have turned out failures. It cannot be too widely known that with the majority of English papers an alkaline silver bath is a sad mistake. Repeatedly I have tried it, and only with the one result: comparative failure. As a rule, I recommend in all photographic operations abstinence from empiric admixture with the active principle that is indispensable in the solutions used; as, for example, for the so-called printing bath, I use nitrate of soda, because it obviates the necessity of using potassium. The solution never discolors, thus proving that the salt described is a practically valuable adjunct. As for the best, because it is a trifling quantity of silver carbonate in winter, and silver just as much in summer, I recommend to Messrs. Johnson and Matthey. I never have occasion to test the bath, add no acid nor alkaline agency, and, by leaving well alone, am rarely troubled with any printing difficulty other than those which arise from leaden skies, pea-soup-colour fog, and other similar uncontrollable enemies to photography. The silver bath should be neutral, or, if any change from that, very faintly acid. The lines produced with paper floated on solutions that are made alkaline with liquid ammonia are in part fugitive, whilst the acid or neutral silver bath, such as just described, gives the requisite conditions for making the colour produced in the gold bath stable and permanent.

A NEW DISCOVERY—

Which, I presume, means that I shall shortly be informed of no end of persons who knew it, but who, being modest, kept the secret for private circulation. A few weeks since I had a rare hunt after the cause of orange-tinted spots of various shapes which occasionally spoiled a few of my prints. I thought at first they arose from the presence in the water of sugar, but "couldn't be, neither—the water was too cold.

Whilst in the act of hanging up the prints one day, however, I noticed a large black spot in one of the sheets, and thought it was smut. On closer examination, I found the substance was solid, with edges jagged and
serrated. Taken between the fingers and removed from the paper, lo and behold! a duplicate imprint was seen on the print: 'twas of the often seen orange hue. On inspecting the solid, I found, 'twas oxide of iron (otherwise the well known iron rust), and I had lighted upon what I now offer as my newest discovery.

I had intended writing of several other matters, but at this instant find that I have already made considerable encroachments on the Editor's patience and space, and must await some other moments of leisure.

PRACTICAL PORTRAIT PHOTOGRAPHY.

BY WILLIAM HEIGHWAY.

INTRODUCTION.

It is with great dilloence that I place before the intelligent photographer a series of articles on his art; but a knowledge, formed by an extensive reading of works already devoted to photography and the complaints I have heard so generally expressed of them, as they appeared—of their too theoretical character generally—gives me that excuse vanity demands, that I shall be able to supply a want.

In a study of photographic literature the reader cannot but be struck with the strange diversity of thought and method in the treatment of almost every detail—chemical or manipulative—of our art, and the beginner, and not infrequently the finished scholar, in trying to follow out the theories and advice of those teachers, has been thrown into a very undesirable state of 'fog,' from whence to extricate himself he has been forced to take charge of the helm for himself, if his knowledge was sufficient, or as is seldom the result, to give up in despair. There is, of course, as those who have succeeded know well enough, a great deal that must be studied individually, and a point where the best book ever written as an ally deserts one. A feeling of independence and spirit of self-reliance are indispensable to the student who would excel.

While success is the reward of patience and studious research, there are still the majority who will ever remain in the rank-and-file, who will ever need counsel and advice; and for these it is necessary to provide simple and intelligible rules of working, and the formation of formulae by which, in following, they may overskip the discouraging impediments which befall the first steps of progress in our art. It shall be my endeavour, in placing these before the reader, to do so in as simple language as possible, without any mystifying technicality, and with just sufficient theory to explain why each manipulation is conducted, and so let the student pursue a course, not because it is so set down, but intelligently, as a means to a certain end, the which he fully understands. This plan, it appears to me, is, not only one called for by intelligent pupils, but a simplification of tuition. First, what has to be done—that understood, how it can be done—and why the means adopted are the best.

I propose, as my plan, to take the reader by the hand, and conduct him step by step through the various manipulations and processes, just as if he were a pupil in a gallery; to fight his way, as the writer has done, from glass cleaning, where he learns his first great lesson that nothing can be done too thoroughly!

He will then be introduced to the Dark Room, and its construction explained. The chemicals will next be brought under his notice, and their use and properties explained, in order that his dark room manipulations may not be groppings in the dark indeed. Here I shall take advantage of the opportunity of impressing on the reader, that whatever may be of service in these pages, may be rendered of no service to the reader who, after once seeing personal, throws it aside, or by a loose and inefficient method of practising the directions here set down, or a slovenly and dirty manipulation.

PRECISION

is absolutely necessary. How is it possible to judge the effect of a formula without a strict adherence to the quantities, to directions, to time, to degrees? Too often has the operator, in the perusal of a book or journal of his art, come upon a formula which promises well; say a developer, than which there is hardly a more delicate agent, liable as it is to variation by heat or cold or any trifling change in the proportions of the ingredients. In consequence of his discovery of a new developer, he takes his iron, perhaps kept in a brown-paper bag, which has burst, or a imperfectly-stored bottle, a percolated bottle, so oxidized as to have assumed a rusty-grey powderly appearance. In weighing out an ounce, he may put in an extra crystal. He solaces himself with the thought, 'that just turns the scale,' and proceeds in like haphazard manner to measure out his acid. Water he scarcely thinks worth taking the trouble to measure. He feels satisfied, and with a too easy conscience proceeds to try this thoroughly original developer. If it answers, he feels pleased, and a glow of self-satisfaction comes over him; but reproduce it he cannot! Or if, as is most likely to be the case, it does not answer his expectations, and the promises made for the developer he has not made up are not realized, he throws it away with the angry remark, 'I never did learn anything from these books—all try any of these formulae again, which is a very wise determination to come to.

But it may happen that he may have taken every care as regards the proportions of the solutions, weighed and measured them out with exact nicety; but he is not a believer in that principal of photographic virtues, cleanliness.

Some foreign substance has been mixed up with the solution, caught up with the iron or organic matter in his bottles, or from his fingers. Then, in the test, the collodionized plate is stained with marks of his dirty fingers; he throws a quantity of the developer over the plate, allowing most of it to spill into the sink, carrying with it most of the silver from the plate, the retention of which is so necessary to a proper determination of the value of the formula—indeed of beauty of the negative—and the result is stains, streaks, spots—and disgust.

You cannot too early or too thoroughly learn these two cardinal virtues of precision and cleanliness. It is observable in every movement of the first-rate operator: the neatness of his person as far as the nature of his work will allow; the cleanliness of the camera, lens, chemical, bath, solution, and what not under his care; and the neatness of the reception, operating, and dark rooms—these are the evidences; the result is perfection. I do not by any means intend to say that a clean and careful operator is always a clever one; but with these qualities he is always at his best, while the talented, slovenly man is at his worst. Even if it does sometimes appear that an admired worker in the dark-room or printing department is not as painstaking as he might be, this is more apparent than real, for some of the hard rules are of necessity relaxed by the master of his business.

Cameras should always be ready for use, free from dust, and in good repair. Spare lenses should be placed where they are not liable to get injured. The posing chair and accessories of the plate house should come to keep such a case; dust and stains, last longer, and present a better appearance to the sitters. When necessary to move a chair, background, or headrest, it can be done as expeditiously quietly, as with a great noise and racket, which not only annoy your customers, but destroy your property.

Order and neatness should reign in the chemical room, and are observable in the arrangement of legible logging of all bottles and other vessels. Funnels should be kept clean and to their proper uses, and the filtering paper...
ready at hand. In the dark room, which has generally to serve as a chemical room, also—though this should not be if it is possible to set aside a separate apartment for the reception of chemicals—there is great scope for the display of neatness and convenience of arrangement. The carriages should stand near the silver bath, which should be kept well covered when not in use, to preserve it from dust.

On a shelf over or beside the sink should be kept the developing solution and glass, free from dirt and crystals of inorganic salt. Collectors' rock glasses should not be constantly cleaned. From this cause alone many negatives have been ruined. The collodion bottles, handily placed, ought to be well looked after; the lip of each bottle on which the collodion collects should be wiped each time after using, thus guarding against any of the spots and stains which so trouble operators. Above all, the floor of the dark room ought to be very clean (mopped out every morning) that, in moving about, the operator does not raise a cloud of dust, the particles of which find their way into bottles and solutions, on to coated plates, and create mischief in a thousand and one ways. Order and cleanliness, in short, should reign supreme.

I am sure no thoughtful reader needs further examples of the mischief done by the neglect of these rules. If the collector in his own business is not seriously minded, let him think of the effect of an overdose of a drug by a chemist in making up a prescription, and in many other ways he may think of in a moment, and let him take the lesson to heart.

I hope this little sermonette has not been preached in vain, but that its lesson will show its work as we go on with our studies. The darkroom work mastered as it can be at this early stage, the student will be introduced to the glass house, to learn its construction, the effect of light on the salts of silver, lighting the figure, and the general work of this department, with a few hints on artistic and

On this head I shall be content to give only some general rules, leaving the higher perfection of the student to his own knowledge of art and many splendid works already written on the subject—notably Mr. Robinson's book on Artistic Photography, which every photographer with ambition to excel ought to possess.

Printing the negative will next engage the attention of the reader; but in this, as indeed in most of the manipulations and processes of our art, practice is the great thing. The pupil must study as much as possible to explain orally, and show the pupil how to do a thing, than it is to write rules and understandable instructions; and it is in this respect that all books of instruction in an art fail to a very great extent.

(To be continued.)

PHOTOGRAPHIC EXPERIENCES IN PARIS.

We have been favoured by Monsieur Adolphe Beau with the following, translated from a French paper:

So great has been the number of photographers in Paris, that should a few of them happen to die off suddenly, it would hardly be noticed. People live long in the photographic line, and perchance they might never die, were it not for ugly women. Ugly women are, indeed, to photographers what parsley is to parrots. Ugly women will be made pretty, and they positively howl when a true likeness is shown to them.

At a study of a photographer of my acquaintance is a lovely beauty of Blanche Pierson (the actress) before the war. It is a coloured, fair, pink, smiling likeness, with a certain piquant and roguish expression; just a little bit of a shoulder, the arm bare, the hand half closed, and, in a word, a pose which in itself may be termed a good—fortune—a god-send.

Then some horrid creature, thin, angular, with a dark yellow skin, a broken nose, and protruding jaw, comes into the studio and undergoes the operation. She has the shoulders bare (churchyard shoulders); uncovered arms (vampire's arms); a hideous and satanic smile pervades her face from left to right; and long teeth, as if made of orange peel, bite her upper lip.

"The proofs are printed. The lady was to come on the following day. She has come. The print has been made to beautify her as much as could be. Lilies and roses have been lavished all over her person. However, she proceeds with darkening eyes and dilated nostrils. "What an awful thing this is!" says she; 'you must have done it on purpose; it is monstrous!' 'Madam,' stammers the photographer, 'we cannot do better.' The lady, suddenly discovering the portrait of Mdle. Pierson, exclaims, 'Look here!—this is how I mean to be.' "Well, then," answers the photographer, 'take this portrait home, and say it is you.'

Correspondence.

PHOTOGRAPHING LARGE GROUPS BY MAGNESIUM LIGHT.

Sir,—Application was made to me a short time since to take a photograph of a fancy ball by the magnesium light. It was proposed that I should be stationed on a gallery, and take a general view of the company. I expressed some doubt as to its success, and was told "the thing had been done," and it was considerably added, "Of course they would have to stand still for a long time." I declined to undertake it. Can you, or any of your readers, inform me whether such a thing has been done successfully?—Your obedient servant,

D.

〔Have any of our readers had experience in this direction?〕

Proceedings of Societies.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The monthly meeting of this Association was held at the Free Public Library and Museum, on Monday, the 6th instant; the Rev. J. D. Betley, President, in the chair.

The minutes of the previous meeting were read and confirmed.

Mr. Houlgrave exhibited a number of negatives to show the excellence and keeping qualities of plates by the emulsion-without-washing process, as prepared by Mr. Bolton's formula. Several of the plates had been kept eight or ten months, and with them were shown companion pictures taken on plates by Major Russell's tannin and bath formula, showing the superiority of the former, although Mr. Houlgrave had previously practised Major Russell's process. He (Mr. Houlgrave) said he had now preferred to use Mr. Bolton's pellicle process to any other he had tried, there being so little liability to stain or spot the plates consequent on the little handling they had in their preparation.

The Rev. H. J. Palmer showed some interiors of Beverley Minster, taken on Kennett's gelatine plates. The exposure had been only one minute ten seconds in December last. Every detail was there, and he (Mr. Palmer) would not have given, with his experience in taking interiors, less than an hour with any other dry plate.

The President then read a letter from Mr. H. Baden Pritchard in reference to a fund that was being collected for the widow of the late Mr. O. G. Rejlander. He (the President) or the Secretary would be glad to take charge of any subscriptions that were sent in.

The members then adjourned to the Lecture Hall for the purpose of holding a "popular" meeting. Here they were joined by a large company of their friends.

The President, in opening the proceedings, said that the late Mr. Rejlander's presentation of a model of the temple of kirthar. He object being more to show a miscellaneous collection of transparencies selected chiefly for their novelty and interest, and also for their beauty and excellence as photographs. The transparencies had been nearly all produced by Mr. F. York, of Notting Hill, London, who had
been wonderfully successful in obtaining from life the portraits of so many of the animals in the Zoological Gardens. Many of these would be shown on the screen, and also a selection of Mr. York's beautiful views of London, India, and America. The members were greatly indebted to Mr. York for his kindness in granting the use of them for the evening. They had also to thank the use of the excellent films and of his excellent views of American scenery, as this would enable Mr. C. Dawson (who kindly undertook the duty of lecturer) to give them a description of a country with which he was intimately acquainted.

Mr. Knott then entertained the company for nearly an hour and a-half with some of the most effective and entertaining of films which are continually manifested by the applause of the audience. The entertainment was rendered all the more enjoyable by the amusing remarks and descriptions of the lecturer, who seemed equally “at home” in America, India, London, or with the animals in the Zoological Gardens.

**Talk in the Studio.**

CERTAINTY AND PERFECT CONTROL IN LIGHTING.—Mr. Vanderwayde has just invented and patented a form of studio, or method of lighting a studio, which gives the most singularly complete control over the direction of the light that can be conceived. Having visited almost every studio of note, not only in this country, but in America and Continental Europe, he has given himself the best of very many of the most successful methods for lighting the sitter, and with the small amount of light reaching the model, compared with the amount reaching the windows of the studio, and with the want of control over the direction of the light generally prevalent; and observation and reflection have led to the invention of a new system. We have just seen, from the model studio we have seen, the concentration of the light and the control afforded are most admirable. All the light entering the studio is of absolute use in lighting the model, who may be perfectly illuminated at whatever point of the studio that it is desired to be placed, and another light or lights, if another light is desired can be placed. The result is to save a huge amount of time and labor, and to get a result as good as is to be had from any other system.

**The Solar Eclipse.**—The Times, referring to the eclipse of the 6th, says:—“The most striking thing about the Royal Society programme is its simplicity. For the first time in Eclipse Expeditions, no eye observations are arranged for; all the phenomena are to be photographically recorded. Here we see the enormous advantage which has lately been made in these studies; for we may remind our readers that in 1871, when the Astronomer Royal was appointed, the theory and use of the spectroscope were in their infancy, and we have no accurate observations of the eclipse of that year, a committee of that Society would not agree to employ photography at all!” An article in the Daily News, accredited to Mr. Proctor, referring to the same subject, says: “From the 26th to the 28th of August next, the transit of Venus may be expected to be accomplished, and the opportunity which it affords of obtaining an accurate measurement of the distance of the sun from the earth, and of observing the effect of the solar prominences and the solar disc, in a condition of partial darkness, will be of the greatest interest to all who have a love for scientific pursuits.”

Good photographs of the corona on this occasion will throw important light on questions of solar physics. The sun during the eclipses of 1870 and 1871 was marked by many spots, indicating a condition of great disturbance. The corona photographed on those occasions was therefore the corona belonging to a disturbed sun. Now it has been noticed by Professor Young, of Dartford College, N.H., that as the spots have gradually diminished in number during the last three or four years, the coloured prominences have become smaller and less brilliant. This effect must be due to the gradual increase of the hydrosphere. As the spots have made their way through the sun’s corostrum, the hydrogen, being the principal constituent of the sun’s atmosphere, must have disengaged itself from the rest of the gas, and have thus increased the surface of the sun. The result has been that the corona has become less brilliant and less extensive, and it is probable that a similar diminution of the corona will take place during the eclipse of 1872.

J. W. DAWSON.—In making the iodide of mercury intensifier to which you refer, the solution of iodine is added to the mercury solution a little at a time, until you obtain the intensity desired, and continue until the iodine has been diluted as much as possible, and the mixture is just as clear as you wish it to be. You may add, almost as durable, as stimulated glass. The addition of dragon’s blood to a deep red-orange plate of orange, can be obtained. For lamp shades the coloured varnish can be applied with a brush.”

**To Correspondents.**

J. W. DAWSON.—In making the iodide of mercury intensifier to which you refer, the solution of iodine is added to the mercury solution a little at a time, until you obtain the intensity desired, and continue until the iodine has been diluted as much as possible, and the mixture is just as clear as you wish it to be. You may add, almost as durable, as stimulated glass. The addition of dragon’s blood to a deep red-orange plate of orange, can be obtained. For lamp shades the coloured varnish can be applied with a brush.”

**La Morale Photographic.**—Our duty enjoins us to make friends of foes, but against it proud science contends; though not meaning the weightier command to oppose. She instructs us to make phase of friends. —Judy.

**Colloclio-Chloride.—Anthony’s Bulletin says:—** “A very good way to make colloclio-chloride of silver print richly and perfectly dark is to put some of it in a bottle, and to desire to use at any particular time, and to add to that a drop or two of concentrated ammonium. It will not do to add the ammonium in any considerable time before using.”

**Blackening Sheet Zinc.**—The following is a new process lately discovered for obtaining zinc sheets of a solid black colour:—The sheet of zinc is cleaned by hydrochloric acid and sand, and then plunged into a solution of equal parts of chlorate of potash and sulphuric acid. A slight velvety-black deposit is immediately formed. The plate is carefully washed with water, allowed to dry, and then plunged into a solution of sulphuric acid, and rubbed with a piece of cotton rag. —English Mechanic.

**How to Glaze a Dark Room.**—Mr. A. W. Bingley says, in the Western Photographic News:—“Dissolve dragon’s blood (which is not expensive, and can be obtained at almost any drug store) in alcohol, and add the solution to a varnish (best made of shellac and alcohol) and you obtain the requisite depth of colour. Varnish your plates of glass with this as you would a negative, and glass your dark room windows with it. The cost is but little in addition to that of the glass, and is as effective, and, f may add, almost as durable, as stained glass. Add a little of dragon’s blood to a deep red-orange plate of orange, can be obtained. For lamp shades the coloured varnish can be applied with a brush.”

**To Correspondents.**

T. M. G.—We have given instructions for producing colloclio transfuse very repeatedly, and cannot possibly devote sufficient space in this column to repeat the details. You will find many articles in the best photographic magazines, which describe the process. In our Year-Book for 1874, page 74, you will find full instructions. We have also given various recipes for the preparation of sodium glass. Orange chrome (ground in oil, and applied to the surface of the glass) added to metallic varnish will answer well.
J. H.—One of the best semi-transparent coatings for partially obscuring glass to obstruct the direct rays of the sun is a dilute solution of starch applied hot.

ADOLPHUS.—There are two reasons for the reticulation of the photographic film. One is to allow the glass to be in constant trouble with direct sunlight. We fear that your aspect will involve some trouble, as the sitter will be illuminated with light from the south-east. You do not state the size or proportions of your projected studio, hence it is very difficult to give you any advice as to the proportion of glass to be employed. Of course both ends will be opaque, and as you build against a wall the west side should be glass. On the east side let six feet next the sitter be end and be opaque, and let the same amount, or two or three feet more, of the roof at that end be opaque. Then have ten or twelve feet of roof and side glass, the glass at the side coming within twenty inches of the ground.

LEARNER.—The collodion peeling from the glass in drying may proceed from various causes. One of the most common causes is the use of a dirty plate. Another cause is under-exposure and under-development. Another cause is imperfect washing of the collodion. Another cause, excess of acid in the bath. The slight crystalline deposit of silver in the shadows may be due to the developer being too weak. Sometimes it is due to the use of a newly mixed developer. Adding a little of an old developing solution will often prove a cure for this in glass positives.

B. K. W.—That marked D of the rapid form, will answer well, or the rapid single lens of the same maker. We have seen some specimens you cannot speak up to its rapidity.

COL. MARSHALL.—Thanks. We published some articles on the subject some years ago, both in the News and Year-Book, but we will give you the subject our attention again.

PERPLEXED.—The defects you described are more likely to be due to the collodion than the nitrate bath. The rotten film, the gray shadows, and other symptoms, all indicate the use of an old decomposed collodion; and such a collodion would tend to produce grey fog and a scum forming in development. This is due to the formation of a chlorid with a phophoric acid, it is only necessary to add the acid to the nitro solution a little at a time, continuing as long as any precipitate is thrown down.

C. B.—The strong affinity of sulphuric acid for water undoubtedly gives the desiccating power to a drying bath. The common oil of vitriol is of a sufficiently uniform strength to answer every purpose. How often it would require renewing could only be ascertained by experience, and, of course, would be governed by the amount of acid used and the amount of aqueous vapour to be absorbed. Whether its efficiency as a desiccator is sufficiently valuable to counterbalance the risks and inconveniences of its use, we cannot say, nor have we any record at hand of its use in drying boxes. We should hesitate to recommend its use. Thanks for the contribution to the Rejlander Fund, which shall be duly handed to the treasurer.

AMATUR.—The causes and remedies for blisters in prints have been much discussed, as you will ascertain consulting recent volumes of the Photographic News. The causes are various, as are, of course, the remedies. In the first place, they most frequently occur in the albumenized paper. Short floating on the silver bath, by which the film of albumen is not thoroughly coagulated throughout, is a frequent cause. Longer floating, or immersing the print in alcohol before toning, is a remedy. Adding alcohol or ether to the hypo bath is found by some to be a remedy. Immersing the print in a strong solution of alum after toning and fixing is recommended as a remedy. Immersing in a strong solution of silver nitrate after fixing and before washing has been found beneficial. Immersing the print in the fixing bath without washing after toning is sometimes a cause, and should be avoided. Sometimes they show after the print is dried, and are then of course, injurious.

C. A. M. W.—We regret exceedingly that the number for Feb. 27, 1874, is out of print, and we do not know of any method of procuring a copy, except the chance of advertising. If we can hear of one it is pleasure in letting you have it.

W. H. M.—The simplest and only efficient plan will be to advertise in our pages for an engagement as assistant operator.

L. L.—Experience along with a satisfactory answer to your query. To decide such a question a long series of comparative experiments would have to be undertaken, and at present we have no evidence. Our prepossession would be in favour of the uranium.

W. H. WATSON.—Many thanks. We reproduce the original article, as you will note, in the present number.

MESSRS. HARVEY, REYNOLDS, AND CO., and J. BYRNE.—Thanks. In our next.

Several Correspondents in our next.

THE PHOTOCO-GRAPHIC NEWS.

Dr. Vogel's Attempt to Photograph the Spectrum of Corona.—Allen Young's Arctic Expedition.

Dr. Vogel's Attempt to Photograph the Spectrum of the Corona.—The task which Dr. Vogel set himself to do on the occasion of the solar eclipse on the 8th inst., is one of the most interesting that has ever yet fallen to the lot of the photo-astrophysicist. He has been familiar with the nature of the Corona of the Sun—that bright halo with which all are acquainted who have seen eclipse photographs,—is the great problem just now before astronomers; and to clear this up satisfactorily we want something more than the report of an observer who has examined the phenomenon by the aid of a stereoscope. In the first place, the time at the latter's disposal is but three short minutes, an ample period enough if it were a question of merely recording the presence or not of the lines of a certain metal; but as it is a close examination of the whole spectrum that is required, and an accurate account of many lines, the task is almost impossible in the short limit available. Dr. Vogel is going to photograph the lines in the spectrum, therefore, and although he cannot reproduce the colours, still the position and nature of the lines in the spectrum upon which the sunlight has fallen will demonstrate plainly what they are. He would, however, merely get a record of one end of the spectrum only if he worked under ordinary conditions; for it is but the lines in the violet and blue (and, perhaps, green) portions that would be impressed upon the sensitive plate. Of the lines in the orange and red he would get no trace, and therefore the most important part of the spectrum would be secured, such as might be of a great aid to the astronomer, but which would not wholly satisfy him. Dr. Vogel hoped that by employing his tinted films of bromide of silver he might be enabled to reproduce the whole spectrum intact, availing himself of the important discovery he made last year. This discovery,—which, our readers remember, gave rise to much controversy at the time,—is the fact that if bromide of silver is tinted yellow or red, it becomes sensitive to the red and yellow portions of the spectrum, the maximum sensitiveness of the plate being for these particular rays, and not for the blue and violet to which ordinary plates are most sensitive. Dr. Vogel found this out only by accident at first, and the fact that the colour which absorbs a certain part of the spectrum, the maximum sensitiveness of the plate is for that special colour. The singular importance of this discovery, which has since been confirmed by the well-known French physicist, Becquerel, is, at once apparent; for we may now be able to get impressions of the yellow and red, which trouble physicists so much, as readily as blue or violet. Dr. Vogel hoped, by employing tinted plates, to reproduce the lines in the red and orange portions of the spectrum of the corona (during the eclipse); and, should he have been successful in doing so, he will be able to lay before astronomers a perfect record of the whole phenomenon, which ought at once to solve the question as to the nature of this atmosphere round the sun. Of course a separate plate must be used for each part of the spectrum, and its fullest detail, and the main difficulty will lie in the amount of exposure at his disposal. Ten or twenty seconds were necessary, we believe, to produce the plates showing lines in the red parts of the spectrum which Dr. Vogel forwarded for our inspection; but to produce these he had full sunlight coming through the slit of his spectroscope. At the time of the eclipse, on the other hand, although he was at liberty to expose for three minutes, he had no actual light coming from the orb itself, but only that coming from the halo or corona around the luminary, which, although bright enough, apparently, has little power compared to the sun itself. Eight seconds, exposure, are necessary to give a detailed image of the corona, whereas we know very well that the smallest fraction of a second suffices to impress an image of the sun upon a sensitive plate. The spectrum of the corona will therefore be very weak compared to the spectrum of the sun itself, and we fear lest the three minutes at Dr. Vogel's disposal will be really sufficient to give him an image strong enough for his purpose. However, it is to make the attempt that Dr. Vogel has made a journey of several thousand miles to a tropical climate at the hottest season of the year, and we are only re-echoing the sentiments of every astronomer and photographer in this country when we express a fervent hope that the worthy Professor's labours will be crowned with success.

Allen Young's Polar Expedition.—The Polar Expedition, under Lieutenant Allen Young, of the Royal Naval Reserve, which will accompany H.M. ships the Alert and Discovery, will comprise a scientific staff of its own, independent of such gentlemen as may be attached to the Government enterprise. A naturalist and a photographer will be included, and already Lieutenant Chermaide, B.E., who accompanied Mr. Leigh Smith in his journey north, and who afterwards returned to the Lisbon laboratory before the Photographic Society, has been asked for advice on the subject, as also Mr. Baden Fritchard, the War Department photographer. Dry plates are to be chosen for the work, but a small stock of chemicals for the preparation of wet plates will be taken, for in the summer weather the temperature will not interfere with the moist films. There will be probable little for the camera to do, however, for although some bold headlands may be met with, capable of giving good pictures, the stretches of snow and ice-fields, when once reached, may be photographed once as well as a dozen times. The open sea which is said to exist at the North Pole itself would certainly be worth while depicting, and we hope that the expedition will be instrumental in bringing us back some characteristic views of the country in those remote regions.

FRENCH CORRESPONDENCE.

M. Leon Vidal, who has been in Paris for some days, has obtained a series of well-merited successes during the present week, of which photography will not be slow in profiting. At the Scientific Congress which took place at Paris, M. Vidal was under the presidency of the Minister of Public Instruction, at the general meeting of the Acclimatization Society, and finally at the last meeting of the French Photographic Society, M. Vidal, who brought with him an album full of specimens of various kinds of his photo-chromic process, received an enthusiastic reception. The first glance at these striking pictures convinced everybody of the part which the invention is destined one day to play in science, public instruction, and industry.

We have foreseen this success for some time past, but this is not all: photochromy has now arrived at such a degree of perfection that it may be worked on a large scale. Men most competent to do so have passed a favourable judgment upon it, and it is with much pleasure and satisfaction that I can announce that the Société Anonyme des Publications Périodiques are now treating with the inventor for practically working the process. This Company has not only considerable relations in Paris and in France, but throughout Europe. Seven journals are published under its auspices, all of which belong to the Company; these are:—"Le Moniteur Universel," "Le Petit Moniteur," "La Petite Prusse," "Le Miroir Illustre," "La Presse Illustrée," "Les Études Illustrées," "Le Petit Bulletin du Soldat et du Marin." Besides the above the Company undertakes to publish on commission many other journals, and among others "Le Moniteur de la Photographie." Every day papers and
prints are issued by the company which may be counted by the hundred thousand, for it possesses printing presses capable of throwing off 24,000 copies per hour. The embryo of the photographic plant is actually under the same roof. The company owns a block of many houses on the Quai Voltaire and Rue de Lille. Photography has a place in its vast establishment, which employs all the graphic processes known; and now photochromy is to find a home here too. All the necessary steps for the installation of the process have been taken so as to work photochromy out of the most perfect equilibrum, for the company does not care for its own wants, but will execute any commission it may receive for the pictures, many applications for the prints already existing.

At the same time that M. Vidal arrived, we had the honour of receiving a visit from M. Ernest Boivin, of Mans, who brought with him the models of two photographometers of which he is the inventor. It is by reason of their excessive simplicity of construction, and the working that these apparatus differ from others, and such essential qualities should assure their success. The first is destined for the purpose of regulating the time of exposure when photographing landscapes, &c., by means of dry plates. It is composed of a little plate of mahogany, five centimetres long and three broad, upon one face of which is placed a sheet of black paper, with a strip of mahogany longer than the mahogany, and does not adhere to it completely, so that between the two may be introduced a piece of sensitive paper. Upon the upper face of the mahogany plate is a little opening, circular in form, which is covered with yellow glass, and, if required, may be closed with a very light shutter of copper turning on a pivot. A washer of sensitive paper, which consists of a piece of paper about a third thick, and the surface of the yellow glass, and a little disc of a lighter tint placed in the centre, permit the light to pass into the space which remains uncovered between the two; the latter represent the two normal tints which correspond to the necessary exposure for architectural subjects or for landscapes with verdure, &c. When you desire to work with the apparatus, the sensitive paper is introduced, and the cap of the photometer is removed at the same time that the lens is uncovered. As soon as the sensitive paper becomes tainted to the depth of one or other of the normal colours beside it, the lens is capped, and the operator knows that the exposure has been exact, and that on development a good negative will be obtained. With the same piece of sensitive paper many experiments may be made, for it is only necessary to see that a fresh piece is brought under the opening every time a plate is exposed in the camera.

The second photometer of M. Boivin is composed of a rectangular box, the form and size of a tobacco box, and acts also in a very simple manner. It is destined exclusively for carbon printing; but without a sketch, unfortunately, it would be impossible for me to give your readers an intelligible account of it. I have no doubt, however, it will be promptly manufactured by photographic dealers.

At the last meeting of the Photographic Society on Friday, M. Fleury-Hermagis exhibited what may be truly termed a pocket apparatus for working with dry plates. The camera is composed of four wooden sides connected with hinges, the extremities of which, required to close on one another, are cut to such an angle that when the box is shut up it is a perfect octagonal shape. Folded together, the sides of the camera take up no more room than a cigar case. The little plank which holds the lens and the focussing glass, or frame containing the dry plate, form the ends of the camera. This is mounted upon a three-legged stand, which closes into the form of a walking-stick such as mountain excursionists use.

What is most curious and new in this apparatus is the way of mounting the lens. Instead of being fixed into a tube and worked to and fro with a rack-and-pinion arrangement, the lens is fitted so as to form a screw of itself, turning in a socket. This is a much more simple arrangement than the ordinary one, and the apparatus can be packed in a closed box. The objects to be photographed are those prepared by M. Himson for his portable apparatus, which I have already described in these columns.

At the same meeting, M. Laurent, of Madrid, exhibited to the Society a numerous collection of prints of large dimensions, representing the principal paintings and works of art in the Spanish museums. The pictures were very fine indeed, and comprised an album of great artistic value, which will be of considerable interest to the student of art and history, for the objects are such as should not be allowed to perish. For this reason it is a matter for regret that the reproductions have been printed by the silver process. M. Laurent would have rendered them far more valuable had he printed them in carbon. We are too well acquainted with his skill as a photographer to admit for a moment that he would have found any difficulty in producing prints by the process, which is now placed within reach of all. Fortunately, there is still time, and we hope that in the next edition of his superb work M. Laurent will not pass over the immense advantages which printing in pigments offers, especially in the production of rare and costly plates.

The Industrial Exhibition of Exports is in course of organisation at the Palais des Champs Elysées, and is daily acquiring more and more importance. Looked upon rather coldly at the commencement, it betokens at the present day considerable activity. I have already said that photography takes a part in the exhibition, and, according to news that have reached me, it appears that the art will occupy a most important position in the same way as it has occupied among our own representa
tives, have determined to send their productions. I do not hesitate, therefore, to ask the assistance of English photographers in making this a grand exhibition, and they may rest assured that they will receive a cordial reception from their French brethren here.

Ernest Lagan.

MY LATE EXPERIENCE WITH THE WET PROCESS.

By Frederick York.*

The subject I have selected is the old, old story, the management and formulæ of our every-day life, which is a subject. I think, we shall have many more years to bother us, although we have been informed on all sides, for the last five years, that the time is not far distant when the silver bath will be a thing of the past. My impression is that many thousand gallons of silver bath will have to be doctored before that time. We see a startling advertisement: "Away with the silver bath, and use dry plates." I am disposed to think this firm's motto is, "Do not be afraid, and do not ask why." This circumstance is pressed home more closely this evening by our friend Mr. Kennet, who is going to show us the future by practical demonstration. This process, like all others, will have to be worked out by some painstaking amateur, for the business man is too much absorbed in other occupations to devote much time to experimenting, unless in a secret process, which seems all the rage at present.

The title I have given to this paper is, "My late experience." I will commence with the glass used. I have
abandoned patent plate, and now use British flatted crowned up to 8 by 6, and for larger sizes machine polished sheet, which is a very good substitute for patent plate, at one-third its cost. The process of cleaning is one recently recommended in the photographic journals—to use a paste of whitening or rouge, allowing it to get thoroughly dry on the glass, and then polishing with absolutely dry cloths. I have had success with a paste to which I have noticed when polishing immediately after using a wet paste, which I used to attribute to dirty cloths or leathers. I have tried albumen in various ways, by coating a wet plate, and applying it to a dry plate; there is such a degree of uncertainty about it that I have discarded it, except to put it round the edges of the glass to keep the collodion from dripping.

There are so many excellent collodions in the market that to give my formula would be superfluous. I iodize a Winchester quart at a time, and always keep one in reserve ripening. When the one in use is empty, I take the ripe collodion into use, and refill the other, which is set aside until required. I find this insures clean work. I am not in the habit of adding additional bromide for particulars, as I only use a quart and a quarter of the ounce (although three grains are generally recommended). I do not notice any increased advantage, even for interiors; but I notice one great disadvantage—a more rapid deterioration of the silver bath. Those who used to work simply iodized collodion and pyrogallic developer must have noticed that the baths now get out of order much more quickly. I remember when I first experimented with bromo-iodized collodion and iron developer, that I could never get satisfactory pyro negatives from a bath that had been used with collodion containing bromide.

This brings us to the third part of the process, the much maligned silver bath, the source of all our woe, as the late Mr. Belgander expressed it; many will remember his delight when the question was once more to be discarded entirely. The system I have adopted will appear rather troublesome, but to me it is a saving of time. In making a new bath, I always neutralize it with oxide of silver, and put it in the sun, and when filtered add two drops of nitric acid to each pint of twenty ounces. I have four Winchester quarts; I use only one, and I seek only to evaporating dish and boil for a few minutes, to get rid of the spirit; neutralize with oxide of silver, fill up the bottle with distilled water, and add silver to make it up to its original strength of thirty-five grains to the ounce, and put it out to sun. This bath now has a rest, and, when filtered, eight drops of nitric acid are added. I never think of using a trial plate, so reliable is the plan. At the end of the season they begin to show signs of getting sandy; I then reduce them by Captain Abney’s process, and make new baths out of old ones. I am disposed to think that I shall now save myself trouble, and adopt Mr. Henderson’s recommendation of adding nitrate of baryta to a sandy bath, which certainly is most effectual. I have tried it with a useless bath, giving myriads of pinholes, and the effect of this is in removing the dirt with the spume. I was reluctant to adopt it, being a soluble salt. I was in hopes sulphate of baryta would have answered the same purpose, but it does not. I submit plates from the same sandy bath, treated with sulphate and nitrate. You will perceive the sulphate has no effect—the bath is the same as before; but with the nitrate the objection is entirely removed. I am not able to explain its action, and trust it will provoke a discussion, that we may know the chemical effects of this most useful adjunct to the photographic laboratory. I do not think we have yet arrived at the cause of a sandy bath. We naturally conclude it is from excess of iodide, as it seldom shows itself until the bath has been in use some time. My own impression is that it is not iodide; for the crystals found adhering to the sides of the bath and bottle are insoluble in a solution of iodide of potassium. The precipitate formed by the addition of nitrate of baryta is not affected by exposure to sunlight. And again, I have strengthened an old bath, working well, and the next day the plates have been covered with myriads of pinholes. I am anxious to know why this occurs, because it is opposed to the theory of supersaturation. Strengthening a bath ought to retard, and not induce, this effect. I hope our worthy vice-president, Mr. Spiller, will be able to enlighten us a little on this most important subject.

I have very little to add respecting the use of the bath. I find that in taking interiors the plates are better for being only a short time in the bath—just sufficiently long to remove greasy lines—and then well aired, by resting on the dipper, and finally re-dipping two or three times in the bath. It is also important to add a quarter of the ounce of the anhydrous, to pack it well with blotting-paper, to absorb all the superfluous solution. I am rather extravagant in its use, as it preserves the carriers and clothes, and prevents stains where working. The following incident occurred at the Albert Memorial in 1872, when the place was swarming with photographers. I always worked there very early—in fact, the earliest—and the police in charge made me clean up all the stains made by others the day previous, before allowing me to commence. We are now arrived at the development. This is a subject I have given great attention to. My experience is at variance with many eminent men. I prefer simply sulphate of iron, and with a small quantity of acetic acid. My plan is to make a half-saturated form, so that one drachm mixed with seven of water makes an ounce of developer. The advantages are, simplicity in mixing as required, and uniform action; for it has undergone the process called ripening, which many regard as valuable for clear pictures. The proportions are:

- Water: 3 parts
- Acetic acid: 1 part
- Half-saturated solution of sulphate of iron

In summer I use one drachm in the ounce, but for interiors, and in cold weather, I use two drachms in the ounce, spirits of wine, quantum suff. The proportions of this developer are about twelve grains of sulphate of iron, seven drops of glacial acetic acid, to the ounce of water. I prefer using distilled or boiled water, or water in which a few grains of nitrate of silver to the gallon have been added, as I have traced pinholes, similar to a sandy bath, to hard water; for after development I still use pyrogallic and citric acid before fixing, and acetic pyro after fixing. In the latter case, I always flood the plate with iodine, to prevent stains, which occur very frequently if not thoroughly washed after fixing. It is most important to use a dilute solution of cyanide after intensifying with acetic pyro, or the negatives will, in time, turn brown, and get so dense that they are useless. I always use cyanide for fixing, as I am reluctant to carry about hypo.

In conclusion, I should like to call your attention to the most perfect non-acetio glass I have ever met with. It is prepared from an alcoholic solution of aurine mixed with collodion, the glass coated in the ordinary way, and afterwards varnished with diluted carriage varnish. I did not get favourable results by dissolving the collodion. I was answered for the old bath I experimented with. I tried smaller quantities, but found, after filtering, that the addition of more nitrate caused a further precipitate, which ceased after five grains were added. I did not use the bath between addition. It is possible that a much smaller quantity may be used."
A NEW DRYING BOX FOR DRY PLATES.

BY W. DALLAS,*

The apparatus consists of a box (A, figs. 1 and 2), in length two feet, eighteen inches in width, and one foot in depth, with a loose lid. One of the long sides is divided about one-third from the top, the parts being hinged together. On a level with these hinges is a glass plate (a b) extending nearly the length of the box, and so as to leave a communication between the upper and lower compartments, into which the interior is thus divided. Heat is applied through a closed boiler, B, ten inches in diameter and six inches deep; in this is suspended an air-vessel (c), eight inches in diameter and about two in depth, the interior of which is partially divided by three partitions, d, e, f, as seen in fig. 3. One end of the air-vessel communicates with a cylinder (C) fourteen inches long and four inches in diameter, in which is placed any hygroscopic substance—such as quicklime—and this cylinder projects beyond the end of the box. At the other end of the box is a chimney (D) communicating with the upper chamber. The whole is supported on levelling screws, for the purpose of adjusting the table, a b, upon which the plates to be dried are laid.

The action of the whole is, that the air entering through the cylinder C becomes more or less dried, and in making its way through the air-vessel c the temperature is raised; on entering the lower chamber at b it becomes further heated by contact with the hot surface of the boiler. The air then passes into the upper chamber, and in its progress towards the chimney will dry anything it meets upon the shelf a b. The passage of the air may be traced by the arrows in the figures. The apparatus easily raises the temperature inside the box 60° above that of the external air. Should greater heat be required, the waste steam may be rendered available by passing it through any length of tin tubing.

ON THE AID WHICH PHOTOGRAPHY HAS RENDERED TO THE FINE ARTS.

BY ALEXANDER HUNTER, M.D.*

When photography was first discovered it was thought that it would eventually rival, if it did not supersede, the fine arts. This it will never do, for several reasons: first, from the limited size; second, the texture or surface of the materials employed; and third, from the deficiency in colour and finish. It may be objected, that photography has not yet had time to be thoroughly perfected and developed, as it is really only an invention of the last half century; while painting, drawing, fresco, modelling, sculpture, architecture, and ornament, with all their multifarious applications and combinations, have been known, practised, and nearly all perfected to a very great extent, nearly two thousand years ago, and some of the fine arts have an un- doubted antiquity of three thousand years; for, if you search through the marginal references of your Bible, you will find that 1045 years before our Christian era, David and Hiram were employed in collecting materials for the building and decorating of the Temple, which was commenced b.c. 1015, and completed in eleven years—modelling, chasing in metals, embroidery, and carving in wood, having all been brought into use for the perfecting of this grand Temple. Shortly after this period, or about 800 b.c., we find that architecture, sculpture in stone, and casting in metals, were brought to considerable perfection in Nineveh, when Jonah was sent to preach repentance. Then at a later date, or 580 b.c., we find Nebuchadnessar setting up a golden image (see Daniel iii. 1) ninety feet in height; and from this period to the second or third century of our era the fine arts appear to have been brought to great perfection in Egypt, Greece, and Italy. I need not enter into further particulars regarding their relative ages, for we have abundant proofs that the fine arts were known, practised, and encouraged, many centuries before photography was ever thought of. Almost every year brings to light new discoveries relating to photography, which prove that as a science it is not yet perfected, while an aid to the fine and industrial arts there is hardly any limit to its applications; and we must all admit that there is not one branch of art or of industry to which it has been applied that has not materially benefited by its use.

If we take a glance at some of the multitudinous applications of photography, we find that although artists are greatly indebted to photography for multiplying, cheapening, and preserving valuable record of what has been done in art, still there are limits or bounds to its usefulness, and, in a few instances, defects which will probably never be overcome; though, even in hazarding a statement of this kind, it may be safer to say that up to this period the following appear to us to be the limits of its utility, and the defects of photography. The members of this Society will perhaps be startled to hear me talk of the limits and the defects of this science, but there is no objection that we are running into a few dangerous and questionable applications—as, for instance, the attempt to produce life-size portraits upon paper, believing that these will bear favourable comparison with nature, or with portraits painted in oil with the hand, drawn with chalk, crayons, or water-colours, or sculptured in marble. The very nature of the materials with which we work shows us at once one of their serious defects, for these life-size portraits always suggest the idea of the sitting being pachydermatous—thick and coarse-skinned—or that he or she has lately recovered from a severe attack of small-pox. Here, then, is one of the limits which ought to be placed upon the practice of photography. Do not attempt a portrait or figure above one-third of the size of life, for, independently of the roughness of texture, there is a feebleness in the light and shade, and often a commonplace vulgarity or vacancy of expression, which are exaggerated by being magnified.

But there is another extreme which is equally vicious, degrading, and commonplace in photographic portraiture, and this is the wretched small cheap and nasty cartes-de-visite, where the face is about one-sixth of a pose, and where the art of the tailor, dressmaker, bootmaker, or hatter are obtrusively conspicuous, or where one-third of the picture is perhaps occupied by a table or a drawing-room chair, with vulgar spiral or commonplace turnery, that detracts from instead of improving the picture. I do not condemn all cartes-de-visite, but I think most people now prefer...
POTASSIC PERMANGANATE AS AN INTENSIFIER.

BY W. H. DAVIES.∗

This question has been again brought under discussion, in consequence of some remarks made by me in a paper read before this Society at a late meeting, in which I characterized the method of intensifying with permanganate of potash as unstable. This remark has been called in question, both at the time of publication and since, by the Editor of the News, Dr. Vogel, and others who hold such positions that what they say must be considered and replied to. In all matters of dispute, the questions at issue must be settled by evidence; therefore a detail of my experiences with permanganate as a toning as well as an intensifying agent may aid in settlement of the case.

Some years ago I was engaged in getting up a lot of trays, and being desirous of giving them a rich golden brown tone, I experimented with a considerable number of toning agents, including gold, indium and gold, platinum, palladium, &c., and finally got pretty near what I wanted in permanganate of potash. The colour was all I desired, and although not completely under control as to uniformity of tint, it was, in this respect at least, as sure as any of the others. Another quality it has for this purpose is the clearing up of the transparent parts of the pictures. After a time I began to suspect that the colour of the trays was changing, and I set to work to find whether this was so or not, and the why and wherefore thereof. A pair of test pictures were made, one of which was varnished, the other left unvarnished; these were exposed freely to light and air, being placed up against the window of the glass house, accompanied by another varnished one, which had been gold toned. The whole of these were wet collodion prints, and as a test another was made and treated precisely as the two first, but varnished and kept away from light, air, and variations of temperature, as far as that was possible to be done. The lapse of a very few months sufficed to show that the first pair of pictures had sensibly deteriorated in colour and quality, while the gold toned picture had not changed at all, or, if so, then it was so little as to be undetectable. The last of these two, the unvarnished plate, next to the varnished one, and least with that which had been shielded from light and air. This deterioration has gone on steadily ever since, until now the one unprotected by varnish is a mere shadow of its former self. This would have been tolerably good proof in most cases, but, unfortunately or fortunately, I was not satisfied to rest with a much more delicate proof, but in the same time, absolutely certain proof of the instability of the permanganate as an intensifying and toning agent.

On the occasion of the marriage of the Duke and Duchess of Edinburgh, about a year ago, I was asked to make the two life-size transparencies of the royal couple on about thirty by twenty inch plates, which I did by the ordinary wet process, and finished them by what I then thought the finest method I had yet hit upon; such delicate brown tints were equalled only by the best mezzotints after Sir Joshua Reynolds; and in doing them I thought I had not only discovered "a thing of beauty," but that it would be a "joy for ever." Alas, alas! I had not to wait a year, a month, a week, a day—no, only a single night—ere the beauty was flown for ever: the exquisite transparency of to-day became, under the influence of burning gas and little care, leaden generation. The combination of superexpose of manganese on a silver basis, together with the added products formed by four hours' combustion of good Edinburgh coal gas of twenty-eight candles' value; and what that may produce, who can judge? The examples are before you, and you can see for yourselves how they have been destroyed, and you see, also, that these two samples have faded in spite of the varnishing.

I have not taken especial care over these examples of the failure of the per-(to)—the super-oxide of manganese as a stable intensifier of the silver image. It may be said that these experiences are of transparencies only. This I admit; but we all know that the conditions under which the respective images of the negative and the transparencies are produced are identical, both being made by the wet process; so that what holds in one case would also hold in the other.

There cannot be a doubt that varnish, and complete exclusion from light and air, do to a certain extent preserve the film of manganated silver, as in the examples I now show, which are prepared in the same way, and finished, rendered air-tight, and, to a great extent, kept in the dark, except when in use in the lantern. These seem to have undergone no deterioration whatever; but that, I submit, is no proof of the stability of the permanganate as an intensifier. I may mention that I have another pair of test examples presently undergoing trial, on which, some months hence, I will bring up a further report.

A VERY SIMPLE AND EFFICIENT ENLARGING PROCESS.

A very curious illustration of the fact to which we have more than once recently adverted, that much valuable matter lies entombed in the journals, comparatively unproductive, for the want of enterprise on the part of some skilled worker to carry the processes indicated from the point at which they had been left by the experimentalist to their highest practical issues; and an illustration further of the independent discovery or re-discovery of a method identical with one of those processes published long ago when it was first communicated. The process of enlarging described by Mr. Blanchard at the Photographic Society on Tuesday evening is, we venture to say, one of the most simple and efficient in existence; and the examples with which he illustrated its capabilities were amongst the finest enlargements we have ever seen. We may go further, and affirm that we have rarely seen landscapes taken direct equal them in some of the highest and most valuable pictorial qualities. The process with Mr. Blanchard is, beyond a question, an original one, and yet it is a process we ourselves worked out and published years ago. It is about fifteen years since we first attempted the process, and a few years subsequently we worked it out and described it in the News. When the question of enlarging was brought again prominently before the public two or four years ago, we were again reminded of the method in question and published it in the Year-Book for 1872. As the article is brief, and contains some suggestions of interest, we reproduce it on another page. Fortunately for the photographic public, Mr. Blanchard hit independently upon the same idea, and has worked it out to a degree of perfection for which we should scarcely have hoped, and to which, in our experimental efforts, we certainly never attained. We say fortunately, because it is so in a double sense: first, because his skill has so fully shown the capabilities of the process; and, second, because, with his characteristic liberality, he gives the results of his experience freely to his photographic brethren. On ascertaining that it had been already published, Mr. Blanchard at once abandoned the notion of bringing the method before photographers as a novelty, and it was with satisfaction that he consented to place before the Photographic Society a process and illustrations for which we feel certain every one present was grateful.

The process briefly stated is as follows:—An enlarged transparency of the full size of the required print is obtained from the negative by the ordinary wet process. This transparency must be perfectly dry, and it is possible, if for any reason it is not, for all the prints finally obtained should be facilitated by the transparency. Slight retouching may, if necessary, be effected on the transparency, but with a good negative this should not be necessary. From this enlarged transparency a print is obtained on albumenized paper by the ordinary method of printing in the pressure frame; and this print is the enlarged negative from which all subsequent prints are to be produced. It is important, therefore, that it be a good print in all respects, clean, sharp, and vigorous. It need not be toned, but simply fixed, and well washed. It is touched as may be required; then washed, to render it transparent, and is straightforwardly ready for printing.

Many of the advantages of such a process are obvious; but there are some not quite so apparent until they have been considered. We shall, therefore, briefly summarize some of the most important advantages.

The process is simple and easy, involving no operations unfamiliar to photographers generally. The negatives are not fragile, and are easily kept in stock.

The negatives are easily retouched with either pencil, stump, or water colour.

Where large numbers are required, nothing is more easy than to produce a number of negatives by printing from the transparency, and so print from a score of negatives instead of one or two.

The negatives can be printed at either side, either direct or reversed.

Paper negatives present the most admirable facilities for double printing, either in such simple form as the introduction of a background to a portrait or a sky to a landscape, or the more elaborate work of producing combination prints and similar photographic compositions. Ordinary methods of masking being employed, paper negatives facilitate the operation; but they present also additional facilities in the possibility of neatly cutting up and joining the various negatives, attaching the portions to a plate of glass, and producing one combined negative for printing at one operation, rather than printing portions of a series of masked negatives in successive operations, with all the care necessary for perfect junction at every printing.

Paper negatives, moreover, possess a beauty essentially their own, and yield prints with a specific texture which generally pleases the artistic eye. The texture need not be either coarse or granular; but it often gives a soft, delicate, atmospheric quality rarely otherwise attained. The examples showed by Mr. Blanchard on Tuesday night showed how finely landscapes produced from stereoscopic negatives, enlarged to sixteen inches by twelve. Without any lack of sharpness or crispness of definition, they all possessed that soft, delicate, painting-like quality which at once charms the artistic eye. In some cases, where the taste has been educated only on photographs, the observer may miss the hard wavy incisive line which charms the technical microscopic eye and disgusts the cultivated artist; but we imagine that few examined the specimens by which Mr. Blanchard's paper was illustrated without echoing the general sentiment that whilst they surpassed by far the greater majority of enlargements, they had rarely been equalled in pictorial qualities by prints taken from negatives direct in the camera.

A FEW MORE WORDS ABOUT DRIED ALBUMEN.

A further examination of the dried albumen to which we referred in our last impresses us more strongly with the numerous advantages it presents, not simply on the score of excellence, but also as a matter of economy and convenience, especially to amateurs—and, indeed, for photographers generally—for except in the preparation of albumenized paper the photographic consumption of albumen is rarely large. The chief use of albumen in the dark-rooms is for employment in preliminary coatings, and in the preservatives employed in many dry plate processes. A
very common form of failure with beginners in applying
albumen to both purposes arises from the albumen
being imperfectly liquified by beating, slight filaments
in the albumen solution causing a speckled deposit
in the plate. The dried albumen before us gives a perfectly clean
lucid solution, and by its use defects from such a cause
become impossible. Frequent failures arise from the
impurity to use a solution which has been kept for
a time, and which does not seem so palpably deteriorated
as to make its condemnation certain. The use, therefore,
of a good brand of albumen impossible is, manifestly, an economical proceeding.

There is, moreover, inevitable waste in preparing white
of egg for use at all times. Besides the risk of occasional
bad eggs, and the waste necessary in removing the germ
from impregnated eggs, there is always considerable waste in
preparing a small quantity of any viscous solution, from the
mode in which it clings to the sides of vessels and other
apparatus used in preparing it. If the whole quantity pre-
pared for use be not consumed, it is not a pleasant thing to
keep in stock, being apt to decompose and cause both
stench and waste. The advantage of being able to
prepare any quantity from a drachm to a pint, of any
strength which may be required, and have it ready for use
at a few minutes' notice, is a gain in convenience and
economy not very easily overrated. The
least sample before us is a really elegant preparation:
clear, bright, and sweet, it dissolved in cold water in a few
minutes, without residue, giving a bright limpid solution
ready for use at once. Even in the small bottles, in which
it is sold at the rate of one shilling and sixpence per ounce,
it is not a dear article; but as it is sold in quantities of
eight ounces and upwards at the rate of one shilling and
fourteen pence per ounce, it becomes very cheap indeed, and absolutely more
economical than fresh eggs to the ordinary consumer.

Mr. Thomas considers one ounce to be equal to the whites
of seven eggs; but as there is the inevitable waste to
which we have referred in preparing fresh albumen, it is
easy to understand that, as a practical fact, one ounce
furnishes more solution than the whites of seven eggs, and
confirms Captain Abney's experience, to the effect that one
ounce of dried albumen is more nearly equal to the whites
ten eggs, giving ten ounces of solution of the
consistency of fresh albumen. We feel, therefore, that we are
doing numerous readers a valuable service in placing
forcibly before them the advantages in cleanliness, con-
venience, economy, and freedom from risk, waste, and
annoyance, which this admirable preparation places in
their hands.

PHOTO-MECHANICAL PROCESSES IN
COMMERCE.

There cannot be a doubt that an extensive opening exists
in this country for the commercial application of photo-
mechanical printing processes. For some singular reason,
while we constantly learn from printers and publishers
that they would gladly avail themselves of any good pho-
tographic process applicable to ordinary press printing,
we also constantly learn from gentlemen associated
with photographic experiments in this direction that they have
processes in every way perfect, and awaiting a fair chance
of introduction, yet very little seems to be done. In America
greater progress appears to have been made, and a daily
newspaper, the Citizen, is illustrated by a process in
which photography plays the initial part. In this country the
Woodbury process appears to be most extensively
used for publication purposes; but the results which have
come under attention lately have frequently been unequal
and imperfect. Photo-photographic processes have also been
used to a moderate extent; but, from all accounts, with
equal uncertainty. Another photographic process, em-
ployed as an aid in illustrating a popular periodical, has, we
have been recently informed, been given up, as more trouble
than hand-drawing. And photo-block printing processes
have hitherto failed to obtain any accepted position in the
printing trade. Perhaps the most interesting application
of photography in this direction is the use to which it is
applied on Punch. The charming illustrations by Du
Maurier are drawn by the artist, on account of some dis-
abilities of eyesight, on a very much larger scale than
they are printed. They are then reduced and placed as usual, in the cutting of the block.

The most successful of the photographic processes pro-
duced by photographic means is that to which the inventor
has given his own name, calling it Dallastype. Being a
secret process, only worked by the inventor, its applica-
tion has necessarily been limited, and the tests of its capa-
bility have necessarily been as limited; but some very ex-
cellent work has been produced by Mr. Dallas himself. A
proposal to dispose of the secret for a sum to be raised by
the subscription of a number of photographers has re-
cently been issued by the inventor. The aggregate price
demanded will probably startle many; but it is argued
that as the cost to each individual will not be large, and as
the process is the result of a lifetime of experiment and
study, the large total should not be considered exorbitant.
This is not, however, a point for us to discuss; we merely
remark that the interests of the public calls briefly before
them. The process is offered to five hundred or more sub-
scribers at £20 each, making a minimum sum of £10,000.
The names of subscribers will be received up to the end of
September next, and, we presume, no sale will be
affected unless the number reaches five hundred. When
the total number of subscribers has been received, and
the money paid, each subscriber will receive a printed
copy of "Directions" for work, and for a guinea extra
may see the process worked, or for five guineas more may
receive three lessons. The subscribers will not be pledged
to secrecy, each one dealing as to him may seem best with
the knowledge he has purchased.

The proposal is, doubtless, a novel one, but it is care-
fully stated, and various reasons given for the mode
adopted in carrying out the project, the document in
which the matter is set forth occupying four closely
printed pages of post folio. Those interested in
the question should carefully read the proposal in detail.

PAPER NEGATIVES FOR ENLARGED
PHOTOGRAPHS.

The following description of a very simple method of
enlargement, referred to on another page, appeared in our
Year-Book for 1872 —

"The simplest method of producing paper negatives with which
we are acquainted is one we have often practised
with success. It consists, first, in producing from the
small negative, a good, vigorous, well-exposed, enlarged
transparency of the size desired. This is easily effected
without extensive or expensive appliances: a small room
the ordinary dark room will often answer—which can be
closed upon; a hole in the floor to admit of the negative;
a good card lens; and a screen upon which to rest the
sensitive plate: the appliances, in short, which we have
before described for producing the transparencies for
Sarony's photo-crayons. Thus equipped, without large
camera or lens, the large transparency can easily be
produced. From this it is simply necessary to produce the
genitive on paper by contact printing. We have found
that a piece of albumenized paper, immersed in the bath
instead of flatting, plain side in contact with cliché,
printed deeply, and fixed without toning, would generally
give a negative of sufficient printing vigour, admirably
suited for working upon, the highest lights being applied
by the pencil. Where sufficient vigour is not obtained by
printing out, development printing may be adopted, the
ordinary calotype formula being used, and a few seconds
only of exposure in the printing frame. We have found that paper prepared with fluoride of silver, printed until a slight image appeared, and then developed with gallic acid, gave an image of fine non-actinic colour, well suited for printing purposes. The paper negative, after finishing and touching, should, of course, be waxed, to render the paper transparent, in the manner generally employed in the calotype process.

 Correspondence.

TOUGHENED LENSES.

Dear Sir,—As it is probable M. de la Bastie's grand discovery of a method of toughening glass without destroying its transparency contributes also to a great increase of density, it has occurred to me to throw out a hint to our friends the opticians to examine the matter with a view to practical applications in their line.

It would be interesting first of all to know the indices of refraction toughened crown and flint glass. This could soon be determined. The non-liability to fracture in a lens, though very important, is of little value compared with improved optical qualities. I should say very few valuable lenses get broken. Still it will be an advantage to have a lens not easily injured.—I am, dear sir, yours truly,

383, Gray's Inn Road, April 10.

DUNCAN O. DALLAS.

PROPORTIONS OF LANDSCAPE PHOTOGRAPHS.

Dear Sir,—As a subscriber to your valuable journal, and being myself a landscape and animal painter, besides a portraitist, perhaps you will kindly allow me a little space to call the attention of my photographic brethren to the great discrepancy that exists between the size of enlargements made, and the canvases that are sold by the well-known firms of Newman, Windsor and Newton, Reeves and Son, Rowney and Co., &c. The subjoined list gives the photographic enlarger's sizes and the artist colourman's, and by your readers will be able to judge that the photographer makes no distinction at all, which there should be, between the human portrait and that of animals—say mounted equestrian portraits, for instance. The thanks of all artists generally are due to Mr. Faulkner for calling special attention to this subject, and it would save a great amount of inconvenience both to the artist and the engraver if the latter would have a list prepared with sizes special for animal and landscape subject's. An artist who thoroughly understood his business would never think of using a 24x18 in canvas for a portrait, or a 21x14 for an animal picture. The Enlarger's Sizes.

I will just mention this, that a negative has been taken of a lady mounted on horseback, and she wishes it to be reproduced in oil colours, with the special proviso that the size of the picture without the frame is not to be more than 21 by 14 inches. The artist who receives the commission can at once obtain canvas measuring that, but he cannot obtain an enlargement from a photograph of that size, the nearest approach to it being 20 by 16 inches. Now the enlarger will say that the last named size is correct; and so it is for human portraiture, but not for animal as well. I see among the photographs lately registered that there are some of a particular hunt. Now it would be almost absurd to enlarge one of these negatives, even to make a perfect composition a picture in oil, or even water colour, of it, and make it the same proportionate scale that you would a life-size head and bust.

Each succeeding year photography is more largely employed by artists, and therefore, for their better convenience, it is to be hoped that the photographic enlarger will issue a different scale of sizes, and not mix up indiscriminately human portraiture with either animal or landscape sizes.

I am, dear sir, yours faithfully,

GEORGE CECIL HANCE.

Jarrow-on-Tyne, Durham, April 12th.

SIZE AND PROPORTION IN PORTRAITURE.

Sir,—Permit me to explain that I apply the term "lanky" to the boudoir size only when it is used for other description of portrait than the whole-length, the especial size for which it was designed by Valentine Blanchard. In talking with him on the subject, I said: "The introduction of a new size which is opposite to one description of portrait cannot but have a beneficial influence upon photography for many reasons chiefly, the difficulty most people experience in standing naturally during the length of exposure necessary in our miserable light; the few photographers who possess sufficient knowledge or skill to make a presentable whole-length picture; the dearth of natural, sensible, or pictorial accessories; the absolute importance of proportion in properly representing the sitter. Considerations will in a short time compel the great mass of photographers to abandon the whole-length altogether, and take refuge in half-length or three-quarter pictures, for which your new size is unsuitable. Then publishers will ruthlessly cut down all photographs from 15 by 10 to 8½ by 6½ to the Boudoir size, regardless of proportion or effect. Manufacturers will play their usual pranks with it, and the average size in every respect, the top arch or elliptical, shaped, absurdly round off the four corners—indeed, every conceivable bad alteration will be made."

Already some of my anticipations have been realized. I saw, for instance, a large figure, which I presume was originally 15 by 12, thrust into the Boudoir size; the head was one-sixteenth of an inch from the top of the picture. Permit me again to say, "Proportion is the basis of beauty, and inferior to the proportions of the canvases employed by the old painters, which, I submit, ought unhesitatingly to be adopted for photographic portraits.

I would ask the manufacturers to consider the height of a man in proportion to his width. If it is necessary to have 7½, 10½ in. by 4½, 10½ in. to represent a whole-length, surely a different and squarer size ought to be used when, instead of size of length, we have the same. The reason, good taste, the teaching of all writers on art, and the works of all great artists, teach this. Ignorance, custom, prejudice, and a mistaken greed of gain are against it.

From personal knowledge and experience, I know how solicitous artists are with regard to the proportion of their pictures, and rightly so; for it is the true proportion of a picture—that is to say, its width with regard to its length—which enables an artist to make an excellent composition. It is the necessary width which affords him the space to give breadth and solidity to his picture; which permits him to balance his masses of light and shadow; contrast, support, convey, the lines of his figure; in fact, proportionate width is an absolute necessity to a fine composition. The late William Essex, the eminent animal painter, once told me that Sir Thomas Lawrence altered the size and propor-
tion of a half-length picture six times before he pleased himself. My father, who also knew Sir Thomas, confirmed this by saying he had seen him add or take away a quarter of an inch from a large picture. Anyone not wilfully blind would admit the importance of proportion if they troubled themselves to think on the subject, or would take a whole-length engraving from a great picture, and proceed, to cut it down to a life size or head size, as is done by printers and manufacturers to photographers. It is not a little strange that while the size of the glass employed in making negatives is in every case good, the finished result is false in symmetry and proportion, due to the malign influence of maskers of frames and albums. I ask, how long will photographers tamely submit to this dictation? That a good album size would be a commercial success I have personal evidence and experience.

Many years ago, disgusted to see my pictures mutilated, and the very part cut off on which I had bestowed my best efforts—viz., the width—I had twenty-five albums made, with three carte-de-visite openings or mounts, proportioned to give the pictures the utmost importance. The first copy I forwarded to you as Editor, and you did me the honour of describing the album in your journal in most favourable terms. Encouraged by your approval, I submitted my album filled with pictures to three of the photographers most esteemed by the public at that particular time. One and all approved: one and all gave the same words and sentiments for not joining in my effort to introduce a good and sensible album. Placed on a table in my reception room, it attracted the attention of the first man of taste who called on me, who immediately wished to purchase a similar album. In this way twenty were soon disposed of, and the purchasers, finding it difficult to fill up the spaces, applied to me to supply them with my prettiest pictures.

For years I felt the favourable influence of those albums. For years afterwards people came to sit to me, in consequence of seeing them. At the same time I induced a manufacturer to supply me with toned cards. He warned me against them: "they would not be liked," &c., &c. But from the moment of their introduction to the present time I have scarcely seen a white mounting card.

I mention these instances to show that a good thing is only to be seen to be appreciated by those of cultivated taste, and they influence the mass sooner or later.—I have the honour to be, sir, your obedient servant,

ROBERT PAULKEN.

BRONZE CASTINGS OF PHOTO-BAS-RELIEFS.

Sir,—Having experimented successfully with a process that gives bas-relief, I wish to reproduce them in bronze. Can you or any of your readers kindly inform me how I can melt copper, tin, &c., on a small scale for the bronze castings?

P. M.

Proceedings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

The usual monthly meeting of this Society was held in the Conduit Street Gallery on the evening of Tuesday, April 13th, Mr. J. Glazebrook, F.R.S., in the chair. The minutes of a previous meeting were read and confirmed, and Captain Horatio Ross was elected a member of the Society.

Mr. Glazebrook read a paper on a new method of enlargement, which will appear in our next. He exhibited some enlarged glass transparencies from stereo negatives, a number of very fine paper negatives made from them, and a selection of exceedingly perfect prints, which were much admired.

The Chairman, referring to the charm of paper negatives, said he had recently examined some carbon prints he had made thirty years ago, and found them as perfect as when first produced; the wax preserved them, and gave them a quality almost like tate.

CAPTAIN ABNEY said that Mr. Blanchard had some time ago told him of this method. At that time he was pursuing a somewhat similar plan, but using dry plates for the negatives. He at once adopted the paper, and was perfectly satisfied with the results, as good as those obtained by the collodion negatives. He might add that, in waxing the negatives, it was a good plan first to wax the blotting paper.

The CHAIRMAN said he employed a tin dish in waxing the negatives.

Mr. BLANCHARD, in answer to a question, said he had generally used albumenized paper for the negatives, but for some he had used a plain paper prepared for him by Mr. Thomas, who added, he believed, a little albumen to the salting solution.

Mr. BROWN remarked that all the specimens were landscapes, and asked if the process was good for portraits.

Mr. BLANCHARD explained that all the specimens were produced two years ago, and he had been so much otherwise engaged since that he had not had time to produce others; but he might say that portraits so produced were even finer than landscapes. He might explain how that the process was not, it seemed, a new one, but had been described in the Year-Book some years ago, as he had recently been informed by his friend Mr. Wharton Simpson. He was not aware of that, but believed it to be original; if he had known, he might probably not have worked it out under the impression that it was new. On learning that it had been published, he gave up the thoughts of reading a paper; but Captain Abney and Mr. Wharton Simpson had so strongly urged him, he consented to read the paper they had heard.

Mr. NORMAN HARTLEY said he had used solid paraffin in place of wax. It was, he thought, better, as being more transparent.

Mr. BLANCHARD had not tried it.

A MEMBER said he tried the recently proposed mixture of caster oil and alcohol, and found it answer well in printing.

A vote of thanks was passed by acclamation.

Mr. J. R. SAWYER then read a paper describing improvements in double transfer carbon printing by the use of Weston’s Burnisher, but it was imperative that the prints should be dried by the fire immediately before burning, otherwise the gelatine image was so greedy of water that it absorbed damp from the atmosphere and rendered burning impossible. The effect in giving transparency, detail, and richness to the shadows was marvellous, and made the prints rival the finest on albumenized paper.

Mr. HOOPER, whilst admiring the results and the promised permanency, could not but think that the future of permanent photography, at least for small pictures, did not rest in carbon printing. The process was too much before its time; in ten years, and time after time improvements were made and brought before them; but still photographers did not take it up. There must be a reason, and, apart from the complications of the process, he could not but think that it was due to the fact that in small pictures, at least, the results were inferior to silver printing. He deprecated attention being solely directed to carbon printing for permanency. He believed that a process was yet to be worked out in which beauty and permanency were fully combined. Without being able to explain the reasons that led him to favor carbon printing, he might remark that the results of that process rivalled any other in beauty, and he believed that, properly worked, they were quite permanent. A small carbon print which the Chairman had been good enough to hand to him was very delicate and fine, but he had fastened strongly to the vulgar glass used to give depth and transparency.

The CHAIRMAN said the carbon process had come before them from time to time, but each time with some definite improvement.
He must confess that he sympathised heartily with every effort to secure permanency. At the same time, the Society gladly extended encouragement to all improvements, and he should be glad to see such a process as Mr. Hooper had indicated, it was by competition perfection was attained, the history of the English microscope affording an admirable illustration of perfect results and of the wide efforts of good men who were determined not to be beaten by each other.

Mr. Blanchard called Mr. Sawyer's attention to the advantages of paper negatives, as superseding the necessity of double transfer. A vote of thanks to Mr. Sawyer was carried by acclamation, and acknowledged in a few words.

It was announced that Mr. Spiller would read a paper on "Recent Advances in Photography" at the Society of Arts on Friday night, and that at the next meeting of the Photographic Society Col. Wortley would read a paper on "Comparative Rapidities." The proceedings then terminated.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held in the rooms of the Society of Arts, John Street, Adelphi, on the evening of Thursday, April 8th, Mr. S. B. Davis in the chair. The minutes of a former meeting having been read and confirmed, Mr. J. Porter and Mr. J. B. Hall were elected members of the Society.

Mr. F. York then read a paper on his experience with the wet process during the past year, and exhibited some negatives taken with a bath giving sandy plates, with the same bath after treatment with barium, and with the same bath after treatment with nitrate of baryta. The last plate was the finest he had made, the second little better, whilst the third was quite clean and free from any defect. He also showed some examples of non-acidic glass made by coating plain glass with a solution of silver in nitric acid, which came out of the bath after washing and was dried with pinholes, although it had been working quite clean before.

Mr. W. Secord mentioned that he had found a decided advantage in the use of methylated spirit in the developer. He had referred to its advantages in one of the Year-Books for three or four years. Referring to the treatment of colloid, he had frequently added bromine with advantage. He put six or eight drops of pure bromine into an ounce of alcohol, and allowed it to stand in the sun for a few days until it became colourless, and then added a few drops to an ounce of silver chloride; it gave sensitiveness and brilliancy.* Mr. Foxley said, in answer to a question, that absolute methylated spirit was not now permitted to be sold. The strength was generally about 65 o.p.

A desultory conversation on the subject of methylated spirit followed. Some members used it constantly in the developer, but did not notice any special effect. Others found difficulty in obtaining this spirit except in the form of "finish," with a certain portion of gum dissolved in it.

Mr. Wearton Simpson suggested that he had found a simple method of making this difficulty. The law prescribed to certain dealers that they must not sell methylated spirit retail without the addition of a certain proportion of some gum, but it did not say what gum. He therefore asked to have gum-arabic added; and as this was insoluble in the spirit, he removed it without difficulty. By this means he had been able to get the developer to which the Chairman had alluded, if he remembered rightly, it was methylated spirit, or wood naphtha, which was said to give the advantages in exposure; not methylated spirit, which was a different thing. Methylated spirit was ordinary ethyl alcohol, with ten per cent. of methyl alcohol added. Mr. Barnes had found positive disadvantage in the addition of methylated spirit to the developer.

A conversation on the addition of nitric acid to the bath, and Mr. Black's extremely acid bath, followed, and on the bleaching of the samples of collodion plates. Mr. York thought that the idea the use of methylated spirit caused the rapid loss of colour after adding iodine was an error. He attributed it to the use of old ether which had become osonized, and this osonized produced the bleaching action.

A conversation on the price of pinholes followed.

Mr. Foxley thought that the pinholes were due simply to excess of iodide of silver, as pinholes were unknown in the old days of simply iodized collodion. He thought the minute crystals formed were probably an iodine-bromide of silver.

Mr. York thought that the precipitate of silver, as the precipitate by the barium addition did not darken in the light.

Mr. Warnack said he had reason to believe they were fulfilled of silver formed by the action of alcohol on nitrate of silver, as he had carefully tested, and found that a collection of the etchings possessed the fulminating or explosive quality.

Mr. Simpson said that the question of pinholes, and their various causes, was certainly a perplexing one, and by no means as yet thoroughly solved. It was not impossible that a compound salt containing both iodine and bromine was sometimes formed; but that excess of iodides alone would produce pinholes he had must indispensible evidence. Something like twenty-two years ago, when the saturation of the negative bath with iodide was proposed, he tried the experiment, and very literally saturated it. To his horror, the plate which came out of the bath afterwards was literally riddled with pinholes, although it had been working quite clean before.

Mr. Waimeir then proceeded to give an interesting demonstration of the working of the galene emulsion process, from the preparing of the emulsion by means of his ammole pellicle, to the production of a transparency by exposure to the light of a gas flame. The demonstration was very interesting, and especially illustrated the sensitiveness of the bromo-gelatine by the extreme darkness necessary in coating, developing, &c., the smallest trace of light producing deep ruby glass being the only permissible illumination in the darkroom.

After a vote of thanks the proceedings terminated.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The ordinary meeting was held at the Memorial Hall on the evening of Thursday, the 8th inst., Mr. W. T. Markly, President, in the chair.

The minutes were read and passed, and Mr. B. P. Gregson, of Blackburn, elected a member of the Society.

Mr. Frankland presented the Society with an oxy-hydrogen lantern, made by Messrs. Pamphrey Bros., of Birmingham.

The President said the members could see before them the handsome present of Mr. Frankland, and would no doubt acknowledge it in a suitable manner.

Mr. Frankland received hearty cheer for his liberality.

There was no special business before the meeting, the proceedings terminated at an early hour.

C. Arly, Hon. Secretary.

EDINBURGH PHOTOGRAPHIC SOCIETY.

An ordinary meeting of the Society was held in G, St. Andrew's Square, on the evening of Wednesday, the 7th inst., Dr. Thomson, the President, in the chair.

The minutes of previous meeting were read and approved, and the following gentlemen admitted ordinary members:—R. Orevatt, Robert H. Alston, William Nelson, Thomas Lymington, W. D. Young, Henry Welsh, and Andrew Slater.

Mr. Black, of 2, George Square, then laid on the table, for the inspection of the members, several folios of photographs which his brother, who had recently brought to Edinburgh. They were principally copies of the works of the ancient masters, including Titian, Paul Veronese, Guido, Michael Angelo, &c., &c., from the best
April 16, 1875.

THE PHOTOGRAPHIC NEWS.

museums, galleries, and churches in Italy, and were intended to
give to those who cannot themselves see those interesting collec-
tions an opportunity of seeing and studying those fine works.
The collection was very admirably arranged, and much surprise
was expressed at the admirable way in which the difficulties of such
reproductions had been overcome.
The following question from the "box" was then read:—
"Can the relative merits of lenses by different makers be discussed at
the Private Members' meeting?"

Mr. W. Newson said that he thought the only answer possible
was No. As a society, it would not be right to pass any verdict
on any question between rival makers. Such a discussion ought
not to be held, unless at the request of one of those concerned. If a
number of people desired to send an appeal to the Society with the
request that it might be tested and reported on by a committee, he
could understand that coming within the province of the Society;
but to the question as put he proposed that "No" be given as
an answer from the Society's point of view.

Mr. W. Dallas then exhibited and described a new drying
box (see page 184) for dry plates, especially gelatine films,
where it is desirable to be able to secure a well-regulated supply
of warm, dry air. The arrangement was much commended, and
an appeal was made to send a gelatine plate in pressure of the
members, there could be no doubt that it would be found to be all
that its inventor claims for it.

Mr. W. H. Davis then read some "Notes on the use of permanganate
of potash as a toning and intensifying agent," and exhibited a
photograph by that process by way of illustrations of his opinions
(see page 185).

Dr. Hunter thought that there was sometimes a difficulty in
attributing fading to its true cause, as he had often found it to
come on when no extraordinary chemical had been used, and in cases
where it returned when a much cheaper process was used. He
thought, however, that in many cases it was caused by impurities in the
washing water. He had found that prints washed with the pure
water from the hills in India stood much better than those that
had been washed in the sometimes impure water of the plains,
and he believed that this was due to the fact that much more
transparency that had been toned with the permanganate salt.

Mr. Tannahill had frequently used the permanganate in toning
and intensifying, but had not paid much attention to its keeping
qualities. He thought, however, that when there was a doubt in the
matter, and as there were plenty of equally useful chemicals, it
might with advantage be laid aside.

Mr. A. S. Mackay wished to call attention to some of the
enlargements exhibited by Mr. Dallas, especially to two from the
same negative, the one touched, the other untouched. The un-
touched was a character and breadth which had been altogether destroyed by the touching to which the other had been subjected.
The touching of such heads should only be attempted by a really skilled draughtsman. He did not, of course, mean to say that all touching should be avoided, but simply to ask the members to look at the pictures on the table, and satisfy themselves as to the amount of character that had been sacrificed, and, if they did retouch, see that it was skillfully done.

Dr. Hunter then read a paper on "The Aid which the Fine Arts has Been to the Photographer" (see page 184), and illustrated it
by a large collection of prints, &c. The paper was listened to
with much attention, and elicited frequent expressions of
approbation.

The Chairman said the meeting had been peculiarly fortunate
in meeting with so much interesting matter before it. Dr. Hunter had
furnished much material for interesting discussion, but the late
hour to which the business had extended would, unfortunately,
prevent its taking place. He then laid on the table some prints
for the Society's album, sent by Marshall Wane, through Mr. Williams, of every form of every plate manufactured by a number of the most of the earliest plates. Mr. Swennerton, at one time a student in Edinburgh, and at present resident in Rome; the group was his last production, and showed evidence of great ability. He (the President) proposed that the thanks of the meeting be given to Messrs. Black, Dallas, Davies, Dukinfield, Grieve, &c., for their kindness in sending material for the album.

The Chairman then read a communication from Mr. Baden
Pritchard, in reference to a proposal to raise a fund for the benefit of
Mr. Rejlander. He wished he had sufficient eloquence to plead
the cause of the widow as she deserved. The Society had recently
shown a sympathy for that of Dunlop, &c., and this act of putting the sympathy into practical effect. What was especially
wanted was the handing over to Mrs. Rejlander the whole of the
negatives left by her lamented husband, and thereby putting her
into a position of honourable independence, and he had no doubt
the Society, or rather the members, would consider it a privilege
to do each their part in the good work.

Mr. H. Davis suggested that the subject be placed in the
billet calling next meeting, and that Mr. Pringle be requested to
act as secretary, to receive subscriptions, and the meeting
adjourned.

The first out-door meeting of the season was held on Thursday
the 9th inst. The members assembled at the West End station at
ten o'clock, and went by Caledonian railway to Colinton, where
the cameras were unpacked and set up, and the work of the day
began. Curiously enough, all the plates on the ground were the
familiar deer and alburnum.

The first exposures were got at the old Snuff Mill, almost the last
of its kind in Scotland; and as it and its vicinity afford excellent food for the camera, nine plates were exposed.

The party then, on the invitation of Mr. Fleming, visited the
interior of the mill; but as the process of grinding the tobacco was
in full operation, they soon sought the open air, with the except-
ion of some half a dozen, who, in spite of the inconvenience,
remained long enough to have the whole process of fermentation,
grinding, mixing, and sifting, explained to them.

From the mill they proceeded up the water-side, by Juniper
Green, to Currie, where the work of the day was brought to a close
on some of the quaint old cottages that lie on the river's bank. An
adjournment was then made to the Baccarat Arms, in which a
pleasant hour was spent, and then the party took the train for
Edinburgh, all highly pleased with the excursion, and hoping that
it would prove a type of many such pleasant excursions that they
would have during the approaching season.

Talk in the Studio.

M. Davenne's Formula.—M. Davenne gives the following
formule, which we feel sure will have a practical interest for
many readers, coming, as they do, from so distinguished a
photographic chemist and so good a practical man—For
the positive printing bath—

Mr. Distilled water ... ... ... 100 c.c.
Silver nitrate ... ... ... 10 grammes
Add a few drops of a solution of carbonate of soda.

We may remark that this addition is made, first, in order to
correct the acidity of the bath, due to the free nitric acid which
common silver nitrate contains; and, secondly, in order, by the
presence of a little lime, to render the bath a little more
neutral, to prevent the discoloration of the albumen. For the toning bath:—

Water ... ... ... ... 1,000 c.c.
Double chlo. of gold and potas ... 1 gramme
Spanish white ... ... ... ... 5 grammes

For iodizing wax paper:

Scumined milk, clarified ... ... 500 c.c.
Potassium iodide ... ... ... 7 grammes
" bromide ... ... ... ... 2"
Sugar of milk ... ... ... ... 10 gramme

This formula will, no doubt, be found good by those who
prepare plain paper for enlargements done by development with
gallic acid.

Toughened Glass.—Upon this subject, respecting which
we gave an extract in our last, a correspondent writes to the
Times as follows:—"'With reference to the theory of toughened
glass,' I venture to suggest that it is the same as that of
Prince Rupert's drops, viz., that by the sudden cooling of the
glass its exterior is contracted to such a degree as to compress the
central portion into a smaller space than it would have occupied if the whole had been cooled gradually. Hence the
centre is in a state of extreme tension, which bursts the drop into minute fragments when the equilibrium between the inside and outside pressures is broken by breaking off the thin end of the
'bub' or by engraving the toughened glass with a diamond.
The glass, therefore, cannot be said to be toughened, but case-
hardened, and hence it comes under the same category as case-
hardened iron, tempered steel, &c. This theory is directly
opposed to that of Dunlop, &c., who considered that the rapidly
cooled exterior, by preventing the contraction of the heated
interior, keeps it in a state of tension, instantly relieved by
breaking the smaller end of the drop. But in this case there
would be no explosive tendency, but, on the contrary,
collapse; whereas the Rupert drops scatter their fragments so widely as to render them dangerous playthings. Whichever be the true theory of the discovery, its applications are so numerous and important, that we may expect that glass will show a larger increase in the use of metal household and artistic purposes. In conclusion, I would suggest that since semi-transparent porcelain differs very little from glass in its composition, it may, perhaps, be possible, by carefully heating valuable specimens of China, and subjecting them to this process, to render them to such a degree that Master-families may see with equanimity her best Sévres or Worcester China service scattered over the floor by her maids or children."

PALMISTRY.—"Mr. Woodbury recommends," says the London Medical Record, "that for purposes of identification (of criminals, for example) it is only necessary to get a distinct photographic, that is, one hand, taken in a strong oblique light, so as to bring out the markings strongly. This will be found in a map, he says, never alike in two persons; no disguise short of actual disfigurement can do away with the difference. Upon this the Standard makes the following comments:—"Mr. W. B. Woodbury's recommendation as to the best means to be taken for the purpose of identifying criminals is one of those suggestions which are theoretically perfect, and practically replete with difficulties. It is doubtful true that no two hands are precisely alike, and that a student of palmistry would be able to detect differences; but at the same time it is probable that a great many of the hands which are habitually devoted to the practice of picking and stealing differ from each other so slightly that none but a scientific person could swear infallibly to a hand from a photograph. At any rate, the ordinary observer there is much more dissimilarity between faces than between hands, and while we can obtain likenesses of the former, it seems idle to seek for the latter. Mr. Woodbury's suggestion is ingenious, but, we fear, not feasible."

PUBLISHING BUSINESS.—In the course of some remarks on this subject in our Philadelphia contemporary, Mr. F. B. Cleland says:—"I am satisfied that it is hard for the public not to know what they want in the way of pictures, and it is for the photographer to decide and show. The public will buy any amount of pictures more than they do if they can be brought to their notice in a proper manner. In 1855 I bought my first 4-4 camera, and it sat in the corner of the operating-room for a month without being used, business, of course, being dull. One day I comenong figured the dividends it was returning me sitting there, and the result was not satisfactory to me. I got it out and cleaned off the dust, and turned over a new leaf. The next week I was a young lady for sale, and when she came in for her cards, I had it framed up on the wall for a specimen; I also had an extra one made for her to buy, but she did not buy, so I gave her the picture. She then purchased a frame, on which I made enough to pay for the camera and everything; besides, I had learned, and that is knowledge, and knowledge is capital. So I tried to figure I was ahead on the transaction. I filed the negative away, and in about six months the lady called to see if I could make six duplicates, also brought her sister to sit to make it, thus making a good paying job. Thus, by keeping my spare time employed in this way, I soon had plenty for my 4-4 lens to do. I think if those who complain of dull business would get out the big camera, or any other camera they have advertised for sale for want of use, and put it to work, they would soon be plenty for it to do. Try for a month by putting a card in your work room headed speculation work, and on it put amount of money received for speculation work. Make negatives of all likely subjects you can get hold of; ask them on the street, or wherever you find them, to come in and give you a check— you want to get out some new styles. Show unfinished proofs, but have them look as well as possible, for it is hard to make folks see what you are going to do by retouching; they generally judge by what they see in the proof.""

FOUNDED GLASS. Useful for screens, etc., is made by laying the glass with a strong solution of sulphite of zinc. The salt crystallizes on drying."

CLEANING SILVER.—A strong solution of hypo-sulphite of soda is excellent for cleaning silver. Cyanide of potassium answers a similar purpose, but, being a dangerous poison, its use is better avoided."

To Correspondents.

* * * Some delay may occur at the present moment in answering correspondents, owing to the absence of the Editor from London. * * *

P. Z.—The reason for the delay in making the drawing in the Art Union connected with the Photographers' Benevolent Association was explained some time ago. You will, however, find an announcement respecting the matter in our advertising columns this week.

CYRIL VANDER.—There is no book published on the powder carbon process. An article describing the details appeared in the Photographic News for 1870, page 243, vol. xiv. It is precisely the same in principle as the powder process of reproducing negatives described repeatedly in our volume for last year, and in our last Year-Book.

ONE IN THE TRADE.—There is no specific law by which the matter can be decided. You can only ascertain by trial. Begin with the thinnest piece of common cardboard, and gradually increase by that thickness until you hit the precise distance. Use cardboard rings in making the experiment.

GUNNER.—Several of those you name are very excellent, but they are not intended for small plates, and, hence, altogether for field use, extreme portability rather than space for working is chiefly considered. That you indicate by D is the most convenient, especially as it must serve the purpose of a dark-room at home, as well as a tent for field work.

A. J. SIMPSON.—P. O. order duly received and passed to your credit. We have no collection of the circumstances you name, and as you give no date we have no close for reference. It is quite certain, if we received any specimens, we should acknowledge them, and if no acknowledgment appeared, that fact may be taken as evidence that the specimens never reached us. We do not know of any method whereby you can obtain specimens of various kinds unless you have some agent in London who will select and purchase them for you. Failing that, if you send a remittance to some photographic publishing house, such as Marion and Co. or the Stereoscopic Company, and ask for a selection of a given kind, you will probably meet with what you wish. We cannot tell you the price, because we do not know what size you require. Card size, the price will be one shilling each. The Photographic News during 1874 had several articles on cameo medallions and cameo vignettes. Our Year-Book for 1874 has an article on the subject, page 117. There is no better bath for toning a rich purple than the acetate bath, but it is necessary to have a fine, brilliant negative in order to secure the richest tones in the print.

A. B. C.—You cannot do better than apply to Mr. Blanchard, 26, Albion Court Yard, Soho. We regret that we have not time to write privately; but we could not give you better advice in the longest letter.

O. A. G.—If you are not familiar with the operations you will find it best and most economical to send to a retailer.

BELOW.—We regret that we cannot give you any technical information as to the manufacture of bellows for cameras.

A. J. F.—Thanks; a copy had been found.

Several notices and articles are compiled to stand over for want of space.

Several Correspondents in our next.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

The Candidates for Admission to the Royal Society—The Rejlander Memorial Fund.

The Candidates for Admission to the Royal Society.—There were upwards of fifty candidates for admission into the Royal Society last year; and as the number elected is limited to fifteen annually, the proportion was about four aspirants to every fellowship. For many years past there has been as large a number of candidates as this for the "blue ribbon" of science, for obviously the more limited and select a body becomes, the more anxious are outsiders for admission into it. It is for this reason that one sees scientific men year after year striving for the honour of a chair in the English Academy, as though, strange as it may appear, it always seems that the longer a candidate waits the less chance he has of election. If a man is not elected after the third year of his being before the Council of the Royal Society, the odds are against his ever being able to secure the letters F.R.S. after his name at all, although, on the other hand, again, he must have secured a very large share of public attention if he were ever to obtain the object of his desires at once. Either he must have made some scientific discovery, the importance of which is still fresh before the world; or he must enjoy a position, or post, such as at once stamps him as a man of superior ability. There were this year several candidates for Royal Society honours known in photographic circles, and we had hoped sincerely that some of them would be among the chosen few. Captain Abney, Mr. J. W. L. Glashier, Mr. Spiller, Colonel Stuart Wortley, and, we believe, Lord Lindsay, were put forward by the Fellows of the Royal Society as eligible men for election into that body. It is a polite fiction, by the way, that no one can nominate himself as a candidate, but must leave the matter entirely in the hands of friends who are already Fellows, and who are supposed to nominate you will. It is a well-known and unasked and unknown to you. This is the theory; but we fancy a candidate is rarely proposed without knowing a good deal more about the matter than one might give him credit for. Captain Abney, it will be remembered, was of considerable assistance to the Astronomer-Royal when arranging the Transit of Venus observing parties; and we see that Sir Richard Airy, Dr. de la Rue, Mr. James Glaisher, and other well-known astronomers of eminence, independently of Captain Abney, he is known not only as a photographic astronomer, but as a chemist, and he received support, therefore, from two parties at once. Unfortunately, there was another Engineer officer for election—General Scott—and this gentleman has been selected, so that Captain Abney cannot now secure the honour until next year. Dr. Dupré's claims as a chemist were also strong; he is known as a practical teacher of the sciences, and also as a sound investigator, some researches he made with cotton having, no doubt, made his name familiar to many photographers. His candidacy was so strongly supported by chemists that he could not but be successful. Mr. J. W. L. Glaisher, the son of the worthy President of the Photographic Society, and, with Captain Abney, a member of the Council of the Astronomical Society, is well known both as an astronomer and mathematician, having been second of his year at Cambridge; and although still a young man, his qualifications for the Royal Society have gained him admission to that body at an unusually early age. Mr. Spiller's name is known to all photo-chemists for his researches connected with the latent image, the preservation of dry plates, and other matters, and his name, like that of Colonel Stuart Wortley, is too well known among photographers to require any comment on our part. The strong alkaline developer of Colonel Stuart Wortley was one of several claims put forward on behalf of that gentleman for admission to the Royal Society. Mr. Roberts, the Chemist to the Mint, is among the selected for admission to the Society, being the only other chemist besides Dr. Dupré.

The Rejlander Memorial Fund.—The Rejlander Fund, which has been started for the purpose of satisfying a few claims that arose during the protracted illness of the late Mr. O. G. Rejlander, and securing to his widow the valuable art negatives that are in existence, is making fair progress, we are glad to hear; and there is every prospect of the efforts of the committee being successful if photographers generally will only take up the matter and contribute donations, however small, to the object in view. The works of Mr. Rejlander are so well known among photographers, and their tendency to improve our art so thoroughly recognised throughout the country, that there are few among us who have not benefited in some way from their teaching, and for this reason, no other request that I can think of would void which his loss has caused among us. We earnestly hope that a handsome sum of money may be raised for the Rejlander Memorial Fund.

ON A METHOD OF ENLARGING.

By Valentine Blanchard.*

Is the "good old times" most of the good old plays commenced with a prologue? My play may be bad; therefore my prologue shall be as long as possible. In the race for supremacy most really good things come in first, by the very force of their goodness, but not always. The reason why the Daguerreotype has become a thing of the past, lies, I believe, in the fact that, whilst, it possessed the "thing of beauty" and, I firmly believe, under proper conditions, might become a "joy for ever," it has not had within itself the power of multiplication. On the other hand, however, that which we know as the Calotype or Talbotype process (and after it, following in the same groove the collodion process) has grown into a gigantic success partly because of qualities, unknown in the Daguerreotype process, which have taken hold of the public mind, but also largely because the power of multiplication is very great. But, after all, these are limited; and, for extensive publication, new methods, such as the "Woodburytype" and "Albertype," have come to the front for book-illustration.

The method of what we call negative-printing took the lead of other processes because of its powers of multiplication; but if, instead of this, we had had in the early days of photography a method of producing a perfect transparent positive as the first product of our labours, and from this we had had the power of multiplying ad libitum our negatives, how much the sphere of usefulness would have been enlarged, and how different would have been the position of photography to-day! By the method I am about to describe, the powers of multiplication are most extensive; for the negatives can be reproduced without limit.

My justification, then, for appearing before you to-night is contained in my prologue. The examples of my method are before you in your hands. From a photographic point they are not superior to two or three other methods of enlargement extensively practised; but for artists they have a quality of texture unknown in other methods. My method of working is, I believe, by several artists of great distinction amongst others, several Royal Academicians. On this question, however, the tribunal is competent to award a verdict; and I await the decision.

The method I have the honour to describe to you is partly based upon a process of enlargement described by me about ten years ago, and held in large popular favour throughout the country as a secret process. In the paper I refer to, I dwelt upon the fact that if a transparency were made larger than the negative required, some of the defects were reduced instead of being increased. This is so clear that I need not now dwell upon this point. I have always had a great affection for paper negatives. I have not yet forgotten my first great delight, nearly thirty

* Read before the Photographic Society of Great Britain.
years ago, when I was permitted to see a paper negative developed; and I can now say, after all these years of experience, that the pleasure now felt in producing a good collodion negative is nothing in comparison to it. I am sure all here who have practised the Calotype process will agree to my words.

Well, now, without more circumlocution, I will briefly describe my process.

I produce at one operation a transparency of the size required. The best method I find for this is to use a reflector of looking-glass fixed outside one of the windows of the studio at an angle of 45°, and using north light only, never sunlight. This reflected light falls on a sheet of fine ground glass, which has replaced one of the ordinary squares of the millboard for the light, and being put on a piece of millboard. A hole of the requisite size is cut in this, and the negative is fastened by drawing-pins to the millboard. The millboard fills exactly the pane of ground glass, the square side of which is, of course, turned outwards.

A long bellows-camera is now brought into position, and a glass transparency is made from the negative. The exposure is very important, and the time can only be learned by practice. The image is developed with a weak solution of iron about ten grains to the ounce; and when the detail is fairly out, a much stronger solution may be employed to give force. I would here say, en passant, that all photographers are much indebted to Col. Stuart Wortley for his demonstration of the importance of strong solutions for giving force after all the details are brought out by weak ones. It is important for my method is that the glass, by a shall have every detail possible, and at the same time as much power as can be obtained. Indeed all the force of a good negative must be there, but in reverse. The transparency must be fixed and varnished in the usual way.

When the varnish is hard, all the transparent spots can be marked; and if the shadows are weak in places, another coating of ink or other colour can be employed either on the front or the back of the transparency. When the print is well washed, it is dried; and now any defects of the opposite kind can be touched out. The next process is to wax the paper negative, to make it more transparent. This is done by aid of a flat iron. The print should be made very hot by the frequent passing of the iron, and whilst still hot rubbed with a cake of white wax; alternate ironing and waxing will soon get a tolerable film of wax all over the negative; but a little skill will be necessary to do this part of the process nicely. The print should now be put between thick blotting-paper, to remove the superfluous wax, and the paper negative is now ready for use as an ordinary printing negative. It should be much over-printed, for the waxing process reduces the strength immensely. The right depth, of course, can only be found out by practice. It will be seen that by this method the original is not used except for the transparency, and that the negatives can be made ad libitum from the transparency by an ordinary printer. If, therefore, a large number of plates are wanted in a hurry, it is only necessary to multiply sufficiently the number of negatives from the transparency to supply the demand.

PHOTOGRAPHY IN PERMANENT PIGMENTS, WITH RECENT IMPROVEMENTS IN AUTO TYPE TRANSFER.

BY J. R. SAWYER.

There is no branch of photography more interesting in itself, and more worthy of consideration, than that which relates to the production of photographic prints in a permanent and unalterable form; and here, at the very outset, it is worth pausing to inquire what effect a statement like the preceding (which implies that photographs are produced in a form otherwise than permanent) must have upon those outside the profession, who are not supposed to know or to inquire too curiously into the modus operandi of a process giving them pictures which seem, for a time at least, to be perfectly unexceptionable. Well, now, without more circumlocution, I will briefly describe my process.

I produce at one operation a transparency of the size required. The best method I find for this is to use a reflector of looking-glass fixed outside one of the windows of the studio at an angle of 45°, and using north light only, never sunlight. This reflected light falls on a sheet of fine ground glass, which has replaced one of the ordinary squares of the millboard for the light, and being put on a piece of millboard. A hole of the requisite size is cut in this, and the negative is fastened by drawing-pins to the millboard. The millboard fills exactly the pane of ground glass, the square side of which is, of course, turned outwards.

A long bellows-camera is now brought into position, and a glass transparency is made from the negative. The exposure is very important, and the time can only be learned by practice. The image is developed with a weak solution of iron about ten grains to the ounce; and when the detail is fairly out, a much stronger solution may be employed to give force. I would here say, en passant, that all photographers are much indebted to Col. Stuart Wortley for his demonstration of the importance of strong solutions for giving force after all the details are brought out by weak ones. It is important for my method is that the glass, by a shall have every detail possible, and at the same time as much power as can be obtained. Indeed all the force of a good negative must be there, but in reverse. The transparency must be fixed and varnished in the usual way. When the varnish is hard, all the transparent spots can be marked; and if the shadows are weak in places, another coating of ink or other colour can be employed either on the front or the back of the transparency. When the print is well washed, it is dried; and now any defects of the opposite kind can be touched out. The next process is to wax the paper negative, to make it more transparent. This is done by aid of a flat iron. The print should be made very hot by the frequent passing of the iron, and whilst still hot rubbed with a cake of white wax; alternate ironing and waxing will soon get a tolerable film of wax all over the negative; but a little skill will be necessary to do this part of the process nicely. The print should now be put between thick blotting-paper, to remove the superfluous wax, and the paper negative is now ready for use as an ordinary printing negative. It should be much over-printed, for the waxing process reduces the strength immensely. The right depth, of course, can only be found out by practice. It will be seen that by this method the original is not used except for the transparency, and that the negatives can be made ad libitum from the transparency by an ordinary printer. If, therefore, a large number of plates are wanted in a hurry, it is only necessary to multiply sufficiently the number of negatives from the transparency to supply the demand.

The late Mr. Blair, in England, and the Abbé de Laborde, in France, almost simultaneously hit upon the same idea of Poitelin’s failure; they showed that the action of the light induces a very thin insoluble film over the whole surface of the picture which had been in contact with the negative; therefore, in order to be able to attack the gradations of solubility corresponding to the gradations of intensity in the negative, the operations must be directed to the back of the picture. To effect this they spread their gelatine on very thin paper, as transparent as possible, and imposing this material upon a negative, with the thin paper in
contact with its surface, printed the image through the thin paper. It is easily comprehensible that by such a procedure the back of the picture could be at once got at for the purpose of development; and the action of warm water proved quite sufficient to remove those portions of the gelatine to which the action of the light had not penetrated, and which were consequently soluble.

From this it will be seen that an Autotype picture is really a relief, the elevations and depressions thereof being due to the lesser or greater penetration of the light into the film, this being in accordance with the gradation of light and shade in the negative: the light parts of the picture are those where the light has had a feeble action; and the greater portion of the gelatine and pigment being washed away in development, the film is so thin in these places as to allow the paper or material upon which the picture is placed to show through, the half-tones and deep shadows being correspondingly made by the varying thickness of the pigment.

Passing over the many ingenious methods suggested for doing away with the necessity of printing through the thin paper by which the gelatine-pigment had been supported, we arrive at the invention and working out of a new and better method of printing in permanent pigments by Mr. Swan, of Newcastle-on-Tyne. This consists in making a tissue of gelatine and pigment by coating a sheet of glass with collodion; upon this he spread his compound, which, when dry, he stripped from the glass. He placed the collodionized side of this tissue in contact with the negative in the pressure-frame. Before development he cemented the surface which had been in contact with the negative, adding the proportion of the paper which the support of the pigment was desired to remain, with some material insoluble in hot water. The development was therefore carried on from the back; and the various grades of the picture appeared by the washing away of more or less of the gelatine in accordance with the gradations of light and shade in the negative. The idea soon struck him that the troublesome method of making the tissue as described could be dispensed with, and that the pigmented compound could be made upon ordinary paper if it were possible to remove this paper before development. It must be borne in mind that an Autotype picture cannot be developed from that side which has been in contact with the negative, because it is covered with an insoluble film, and that the action of the light penetrates to a greater or less depth into the gelatine according to the intensity of the action. It would follow from this that if the compound was in sufficient thickness on the paper, the light would not anywhere penetrate its entire depth; and as there would be a film of total insolubility on one surface, there would be a layer of complete solubility on the other.

Mr. Swan coated paper with the pigmented gelatine of considerable thickness; this, when dry, was exposed under a negative to the action of the light; and, before development, it was coated with a solution of india-rubber, and laid upon a piece of paper similarly treated. The two were then pressed into contact by means of a rolling-press. On placing these conjoined sheets in warm water, the soluble layer of gelatine in contact with the paper upon which it had been spread (that is, at the back of the picture) became washed away by the action of the water, allowing the paper to be stripped off, thus leaving exposed the back of the picture, which the action of the water speedily developed, by removing that portion of the gelatine which still remained unacted upon by light, and therefore retained its original solubility.

But here another difficulty presented itself. A little consideration will show that a picture so produced (if from a negative taken from a mirror) will be reversed. To remedy this Mr. Swan carried on the operation one step further; he coated paper with gelatine treated with alum, so as when dry to form a nearly insoluble compound. Upon this paper, in a moistened condition, he laid down the developed picture, to which it adhered firmly, the picture being now imprisoned between two pieces of paper. When dry, the india-rubber coated paper covering the face of the picture was moistened with benzoin, which, dissolving the rubber, allowed the paper to be peeled off, disclosing a photograph in permanent and unalterable pigment.

Without doubt Mr. Swan succeeded in working out an absolutely perfect method of producing photographs in permanent pigments; but at the same time it cannot be denied that the method was not an easy one. It involved the use of costly apparatus, and it was scarcely calculated to meet the wants of those members of the photographic profession who contemplate the printing of permanent photographs from their own negatives.

(To be continued.)

ON THE AID WHICH PHOTOGRAPHY HAS RENDERED TO THE FINE ARTS.

By Alexander Hunter, M.D.*

We must now proceed to particularise, and to describe by photographs which I shall now hand round, some of the most useful and applications of the art, for that it is now a branch of the fine arts, and one of its most valuable conjoiners, every artist must admit. At the same time, I hope to be able to satisfy our photographic friends that the fine arts have some advantages, amongst which must be classed a larger, grander, and nobler field for the display of their talents; a wider field, both of vision and of application; a more delicate refinement, both of sentiment and of observation; and lastly, it allows the artist to abstract from nature beauties of outline of form, of light and shade, and of colour, which, if not so early of attainment in photography, have hitherto been not so successfully mastered.

On the other hand, while we claim for the fine arts the higher place in relation to deep thought, delicate refinement, and powerful expression, we must not overlook the fact that photography can also boast of being able to catch delicate feelings and passing emotions and efforts, and to give them a wonderful reality and permanence. Here, however, it is that the difference is apparent: passing actions, sentiments, or emotions must be well and truthfully represented, or they cannot be got in the camera. In fact, we must have the good actors, or we do not get the good pictures; and besides these, we must have the good manipulator, the skilled chemist, and the eye that can catch the tasteful arrangements, grouping, and the subtle indications of detail to make up a picture. The artist, on the other hand, has the power to select beauties, reject deficiencies, omit redundancies, and to refine and combine all the varied agencies of his art. Some of these the photographer must take as they come, and to his sorrow he finds that all nature is not suited for his art; that very little of it is perfect, and that little is often very difficult to combine harmoniously.

But I can better explain my meaning now by coming to particulars and comparisons. One of the grandest applications of photography has been the reproduction of the frescoes of Michael Angelo, Raphael, Correggio, and the Italian masters. Some of these are fully more pleasing now than the frescoes themselves, as the latter have suffered most materially from dampness, and the surface layers of dust and dirt have been removed by the chemical action of the water. But we have the power to return it to the artist whose work is thus preserved, in its original beauty and perfection, and this is a great advantage.

Much attention has been paid to the reproduction of the great antique statues and monuments, and we have here an opportunity of seeing how well the result is. Some of these statues, it is true, have suffered much from corrosion, and would have been lost forever, but the chemical power has been a great blessing in preserving them for future ages. The result is very pleasing, and the bas-reliefs and alto-reliefs can be represented with great

A VERY SIMPLE AND EFFICIENT ENLARGING PROCESS.

A very curious illustration of the fact to which we have more than once recently adverted, that much valuable matter lies entombed in the journals, comparative unproductive, for the want of enterprise on the part of some skilled worker to carry the processes indicated from the point at which they had been left by the experimentalist to their highest practical issues; and an illustration further of the independent discovery or re-discovery of a method identical with those processes published long ago without fructifying, was recently published. The process, an enlarging described by Mr. Blanchard at the Photographic Society on Tuesday evening, is, we venture to say, one of the most simple and efficient in existence; and the examples with which he illustrated its capabilities were amongst the finest enlargements we have ever seen. We may go further, and affirm that we have rarely seen landscapes taken direct equal them in some of the highest and most valuable pictorial qualities. The process with Mr. Blanchard is, in a word, a question, an original one, and yet it is a process we ourselves worked out and published years ago. It is about fifteen years since we first attempted the process, and a few years subsequently we worked it out and described it in the News. When the question of enlarging was brought again prominently before the public three or four years ago, we were again reminded of the matter, re-visited the question, and published it in the Year-Book for 1872. As the article is brief, and contains some suggestions of interest, we reproduce it on another page. Fortunately for the photographic public, Mr. Blanchard hit independently upon the same idea, and has worked it out to a degree of perfection for which we should scarcely have hoped, and to which, in our experimental efforts, we certainly never attained. We say fortunately, because it is so in a double sense: first, because his skill has so fully shown the capabilities of the process; and, second, because, with his characteristic liberality, he gives the results of his experience freely to his photographic brethren. On ascertaining that it had been already published, Mr. Blanchard at once abandoned the notion of bringing the method before photographers as a novelty, and it was with all satisfaction that he consented to place before the Photographic Society a process and illustrations for which we feel certain every one present was grateful.

The process briefly stated is as follows:—An enlarged transparency of the full size of the required print is obtained from the negative by the ordinary wet process. This transparency must, as far as possible, be facsimiles of the transparency. Slight retouching may, if necessary, be effected on the transparency, but with a good negative this should not be necessary. From this enlarged transparency a print is obtained on albumenized paper by the ordinary method of printing in the pressure frame; and this print is the enlarged negative from which all subsequent prints are to be produced. It is important, therefore, that it be a good print in all respects, clean, sharp, and vigorous. It need not be toned, but simply fixed, and well washed. It is touched as may be required; then waxed to render it transparent, and is straightforward ready for printing.

Many of the advantages of such a process are obvious; but there are some not quite so apparent until they have been considered. We shall, therefore, briefly summarize some of the most important advantages.

The process is simple and easy, involving no operations unfamiliar to photographers generally. The negatives are not fragile, and are easily kept in stock. The negatives are easily retouched with either pencil, stump, or water colour.

Where large numbers are required, nothing is more easy than to produce a number of negatives by printing from the transparency, and so print from a score of negatives instead of one or two. The negatives can be printed at either side, either direct or reversed.

Paper negatives present the most admirable facilities for double printing, either in such simple form as the introduction of a background to a portrait or a sky to a landscape, or the more elaborate work of producing combination groups and similar compositions. If the ordinary methods of masking are employed, paper negatives facilitate the operation; but they present also additional facilities in the possibility of neatly cutting up and joining the various negatives, attaching the portions to a plate of glass, and producing one combined negative for printing at one operation, rather than printing portions of a series of masked negatives in successive operations, with all the care necessary for perfect junction at every printing.

Paper negatives, moreover, possess a beauty essentially their own, and yield prints with a specific texture which generally pleases the artistic eye. The texture need not be either coarse or granular; but it often gives a soft, delicate, atmospheric quality rarely otherwise attained. The examples showed by Mr. Blanchard on Tuesday night were chiefly landscapes produced from stereoscopic negatives, enlarged to six-inch or eight-inch prints by twelve. Without any lack of sharpness or crispness of definition, they all possessed that soft, delicate, painting-like quality which at once charms the artistic eye. In some cases, where the taste has been educated only on photographs, the observer may miss the hard, wiry incisive line which charms the technical microscopic eye and disgusts the cultivated artist; but we imagine that few examined the specimens by which Mr. Blanchard's paper was illustrated without echoing the general sentiment that whilst they surpassed by far the greater majority of enlargements, they had rarely been equalled in pictorial qualities by prints taken from negatives direct in the camera.

A FEW MORE WORDS ABOUT DRIED ALBUMEN.

A further examination of the dried albumen to which we referred in our last impresses us more strongly with the numerous advantages it presents, not simply on the score of excellence, but also as a matter of economy and convenience, especially to amateurs—and, indeed, for photographers generally—for except in the preparation of albumenized paper the photographic consumption of albumen is rarely large. The chief use of albumen in the operating room is for employment in preliminary coatings, and in the preservatives employed in many dry plate processes.

A THE PHOTOGRAPHIC NEWS. [APRIL 16, 1875.

Vol. XIX. No. 807.—APRIL 16, 1875.
of work you cannot stop to choose your plate. Every piece should be fitted into the carrier, for nothing is so annoying as to find, when a plate has been coated and sensitized, that it is too large or too small to rest in the carrier.

The Method of Cleaning the Plates.—Having ascertained that each piece of glass is perfect and properly fits the carrier, roughened round the edges to guard against cutting the film and damaged, and then rinsed under the tap to remove from their surfaces the dust and straw of their packing, they are placed, one by one, into an earthen pot of undiluted commercial nitric acid, that the acid may gain free access to all parts of the glass. With new glass, an hour or two will be sufficient. They are then thoroughly washed under the tap, and albumenized.

The Albumen.—Dissolve the white (perfectly free from gorms) of one fresh egg—ordinarily about an ounce—in twenty ounces of water. A large stoppered bottle is the best thing, in which is placed half a handful of broken glass; this, when the bottle is shaken, serves to cut up the albumen, so that it mixes with the water. When shaken into a stiff froth, sift the bottle upside down over a filter of clean sponge or a clean lamp, and line it up to clean bottle. This solution should be perfectly clear, but with the eggs not perfectly fresh it generally presents a milky appearance. In this case add a few drops of ammonia. This will in most cases clear it perfectly; if it does not, a second filtration will accomplish it. For pouring the albumen on the plate, a graduate will be found handy. The plate has been cleaned in the acid and washed, and should not have been allowed to dry, as so often appear from unequal drying, which it is afterwards impossible to remove. For albumenizing, however, it is imperative that the plate be wet and clean. To insure against grit from the running water, tie up the tap at which you are washing with two or three thicknesses of cotton linen to act as a filter.

Hold the plate horizontally, resting on the edge of the first finger, the thumb over the edge of one corner holding it firm. At the corner, diagonally opposite that held, the albumen is poured on, the graduate being brought as nearly as possible, without touching, to the surface of the glass, to prevent splashing. The plate is tilted that it runs toward the opposite corner, then to that held by finger and thumb. This is actually allowed to drain off at the other corner. Do not pour the whole solution, which you can see dripping the water before it, and do not suffer it to run over the edges. The beginner will on his first trial recognize the fact that although this sounds easy enough, the performance is by no means a simple one, until experience has been gained. Indeed it is almost absolutely necessary in this operation, as well as coating the plate with collodion, and, completely covering the exposed plate with developer, to see it done by an experienced operator, before success can be attained. The plate is, when albumenized, placed in a rack, the corner at which the albumen has been allowed to run off being placed lowest, that it may drain and dry spontaneously. The surplus albumen has been allowed to run into the sink, as from the inexpensive character it is not worth preserving. As the surplus is again plate, however dry you can put them together without fear of injury. Stand them on end in your cupboard—albumen side inside—ready for use. Guard against damp. Stood up close together they are safer from dust than in a rack, and it is only dampness, a fatal enemy, you have to guard against. If, however, a doubt should at any time arise as to which side has been albumenized, you have only to breathe on the glass on the uncoated surface the breath lingers a moment or so, but scarcely an instant on that side coated. For Old and Used Glass it is necessary to have a strong solution of concentrated potash. As with the acid, this solution must cover the plates perfectly. In about twelve hours the old varnished films will float off under a stream of water. The plates are then immersed in the acid solution, and, after a rather longer stay in it than in the case of new glass, they are treated in the manner already described for new glass.

There still appears to linger some prejudice against the albumenizing of glass plates—a groundless one, I venture to think. It is urged that the ammonia which it is necessary, in most cases, to use in the albumen solution injures the silver bath as it does the hand; if it is done carefully, cannot see how any of it can touch the silver solution, as the substratum of albumen is entirely covered by the collodion film. The method, however, says so much unpleasant and really hard work, and is so uniformly certain in working, that it more than compensates for the little injury, if any, done to the silver bath.

The learner having seen how to coat his glass plates will soon acquire the skill and facility in that most important operation, we may safely introduce him to the scene of his future trials (certain) and (let us hope) triumphs—

The Dark Room—that he may study its construction and understand the work of its various parts. First it will be observed that it is dark only in name.

The door closed, he is able to read in any part of it, but the light is coloured orange or yellow in a manner, to his unmingled eye, suggests a dark room. No cracks must be left open; doors must fit well, and every place of ingress of white light be carefully guarded. The dark room should also, if there is any chance for such a distinction, be the most orderly and cleanly room in the gallery, and with as few shelves as possible, for they harbour dust. The less room (consistent with ease and comfort of working) allotted to this department the better. It should have a convenient and ample supply of water, well under control; a large tank or trough occupying the middle of one half of the side of the room; on each side a shelf—one for the bath, but well out of reach of splashes from the water, developing, and so on—and the other for the developer, developing glass, intensifying solution, and silver. In addition to these, all that is requisite in this room is collodion, pouring bottles, the negative glass, and the carriers.

C is the little shelf for collodion and glass plates, near the door, that in coating the plate the operator may have light. The plate coated, he turns round, and two steps bring him to BB, the baths, into one of which he slowly and steadily, without stoppage, lowers the collodioned plate. Properly coated, the plate is withdrawn and placed in the carriers or holders at H, then taken out to the camera. The exposure made, the operator returns the carrier to its place at H, takes out the plate, which he develops over the sink, B. Water is here laid on, the fawcet, F, being conveniently to hand. The operator in a dark room of this construction has not to race all over the room at each process, but can quietly, and, without disturbing any dust, follow each manipulation by walking only a step at a time.
iodised collodion was solely used, and the bath was universally saturated with iodide of silver, pinholes were unknown; and he was disposed to believe that the deposit on the plate producing pinholes was an iodo-bromide of silver. This may on occasions be true, but the premises are scarcely exact. In the earliest days of the collodion process the practice of saturating the bath with iodide of silver was not thought of. It was, if we remember aright, suggested by Mr. T. R. Williams in the year 1853 and the same year the district of Belgium was due to Mr. Thomas. Pinholes, although much less common, were not quite unknown. As we mentioned at the meeting, the first example of pinholes which we ever saw was in the early days of the collodion process. When the recommendation to saturate the nitrate bath with iodide was first made, we tried the experiment, securing thorough saturation. The result was a plate literally covered with the clear transparent spots only too well known now as pinholes; excess of iodide of silver being clearly the cause then, as it has been in thousands of cases since.

It is not unnatural, perhaps, to attribute all defects of apparently one character to one cause, and hence the common tendency to regard all pinholes in negatives as due to one cause. Having traced them in many cases to excess of iodide of silver, many of the habits of pinholes as due to that cause; whilst, on the other hand, pinholes having been found where it was scarcely possible excess of iodide of silver could exist, there is danger of coming to the conclusion that excess of iodide of silver and pinholes had no legitimate connection. Pinholes undoubtedly arise at times from other causes than excess of iodide. In the case it seems very probable that the defect was due to this cause. The result of the successful remedy applied suggests, indeed, another cause. Mr. York added nitrate of baryta to an old bath giving a sandy film and multiplicity of irregular pinholes. The result of this addition was a precipitate, which, when removed by filtration, left the bath in perfect condition, giving plates clean and free from defect. The most legitimate conclusion from the formation of a precipitate on the addition of nitrate of baryta is, that sulphate of silver was present in the bath, and that being decomposed at once on contact with the baryta salt, sulphate of baryta was thrown down, and the bath was so purified of the deleterious matter. Some eight or ten years ago Dr. Vogel traced pinholes to the presence of sulphate of silver, and proposed nitrate of silver to be added so as to form a precipitate 

THE WET COLLODION PROCESS.

A NARRATIVE of the experiences of any successful worker in the most familiar and extensively practised of all photographic processes, the wet collodion process, is always certain, despite its familiarity, of an attentive and interested audience, and rarely fails to evoke an animated interchange of opinions and information in a photographic meeting. Mr. York's paper at the South London meeting, dealing with his recent experiences with the wet collodion process, in which he declared that he had "no new thing to tell, only the old, old story, the management and formulae of every-day life," which every photographer is interested in. The journals have for years past abounded with hints, suggestions, and information; and the great advantage of a paper like that of Mr. York's is, that it gives the successful results of those novelties which a skilful worker of extensive experience has tried.

Commencing with the cleaning of the plate, Mr. York has not been successful in using a substratum of albumen. Which formula he used was not stated; but we may suggest that if the dry albumen described in a former number, in very dilute solution—say one grain of the dried albumen to the ounce of water, and applied to the dry cleared plate with a "Blanchard's brush"—it would be difficult to fail. The mode of cleaning the glass, adopted by Mr. York from some recent suggestion in one of the journals, is one the excellence of which we can strongly commend. We first employed it nearly twenty years ago, and used it for many years with great satisfaction. We employed sometimes rouge, sometimes whitening, sometimes rottenstone, generally making it into a cream with methylated spirit and water. The plates were rubbed well with the mixture, which was then left on the glass to dry, being subsequently polished off with a soft linen cloth, or a soft, clean, dry wash-leather. The glass so treated was always perfectly and satisfactorily cleaned. There was one slight drawback to the method which may easily be guarded against. In the first place, if the final polishing away of the dried whitening, or whatever it is the operating room, the detached particles of dry powder floating about in the air were sometimes troublesome; and next, if the glass were roughed at the edges, particles were apt to adhere, and so contaminate the bath.

In dealing with the nitrate bath, the ever-recurring subject of pinholes arises. Mr. York attributes pinholes to something other than the supersaturation of the bath with iodides, use: bromide and iodised collodion is in some way associated with the production of pinholes. Mr. Foxlee held a similar view, saying that in the earliest days of the collodion process, whilst simply
presence of bromide in the minute crystals causing the pinholes has never been traced, and further that bromide of silver, unlike iodide of silver, is not soluble in solutions of nitrate of silver. Whether the double salt of iodide and bromide of silver may be formed and become the cause of pinholes remains a subject for investigation. It should be remembered that another and perfectly explicable cause for the greater prevalence of pinholes at the present time, than formerly, exists without referring it to the use of bromides. It is admitted that whatever may be the ultimate cause, bromide of silver has given to the use of a bromide bath and worked bath; and there is little doubt that the enormously increased production of negatives in this day, compared with that of (say) sixteen years ago, when the use of bromo-iodized collodion began to obtain, and the rapid over-working of baths in consequence, will explain much of the greater prevalence of pinholes now than in former days.

This reference to over-worked baths brings us to the really practical part of the question. As a member observed at the meeting, he had never met with pinholes except in an over-worked bath, and the really recognized treatment of dilution, sunning, and strengthening, never failed to restore the bath to good condition, and remove the pinholes. Mr. York meets the practical part of the question by describing the double action of an inhibiting agent, nitrate of baryta, adding five grains to the ounce to the defective bath. His practice of keeping a large quantity of solution in alternate use and rest is also strongly to be commended. Another remedy, described in our columns some time ago, has been found most efficacious. It simply consists in adding a few drops of hydrochloric acid to the bath, by which a precipitate of chloride of silver is formed, which carries down with it the cause of the effect defective, and restores the conditions by which clean and spotless negatives are obtained.

SOME RECENT ADVANCES IN PHOTOGRAPHY.

The perusal of Mr. Spiller's paper before the Society of Arts, on Friday evening last, possessed some special points of interest, beyond those involved in the improvements he recorded. It is only by looking back, and fixing the eye upon the well-defined landmarks, that an estimate of the rate of progress can be made. And as in the Society of Arts the Photographic Society had its birth two and twenty years ago, the history of the art during that time may be regarded as fairly indicating the character and extent of the advance really made. It is worthy of remark that whilst there has been improvement in every direction, and many actual gains in the shape of discovery and invention connected with various branches of the art, in its main features it remains unchanged. The wet collection process is still the universal method of producing negatives for all general purposes, and the ordinary method of silver printing in vogue twenty years ago has not yet in any important degree been displaced. That there has been enormous improvement even in these methods, which retain their position with such tenacity, there is little room to doubt, but it is in the various added facilities, in the new processes, and the extended applications of the art, that its secured gains are most manifest, and it is as a record of these that Mr. Spiller's admirable paper possesses especial interest and value.

Without attempting to add anything to Mr. Spiller's excellent resume there are a few points in which it is desirable that the statement of facts should be modified. In assigning discoveries and inventions to their originators, Mr. Spiller adopts the wise and just principle of recognizing the primary claims of the worker-out of a process, rather than the intangible claims of those who may have made vague and nebulous suggestions, or made equally vague and unsuccessful experiments. But in referring to the collodio-bromide emulsion process of Messrs. Sayoe and Bolton, it is suggested that this discovery of the process was a sequence upon our own introduction of the collodio-chloride process. So far as we remember, without having facilities at hand for verification, the collodio-chloride and the collodio-bromide processes were introduced as nearly as possible simultaneously. Emulsion processes had been attempted many years before, especially with iodides and bromides; but no successful method of producing negatives with such emulsions had been discovered until the collodio-bromide emulsion process of Messrs. Sayoe and Bolton was invented. The idea of a collodio-chloride process had not been suggested, except in the frankly confessed failure of M. Gaudin, whose experiments in the production of emulsions, whilst very interesting, did not lead to practical issues.

Referring to the most recent improvement in carbon printing, it is important, duly to appreciate its value, to unmask its precise relation to the method which has been in use for the last few years. The difference between the use of a rigid support, and a flexible support, for the film during development, scarcely accurately, we think, indicates the distinction. Mr. Johnson's improvement did not consist simply in introducing a rigid support; in fact, rigidity simply was no part of his claim. It was the method of adhesion of an impervious substance, with an elastic surface, which constituted the real basis of his improvement. So far from a rigid support constituting the real claim of his patent, he also claims in the specification the use of flexible supports, admitting of the same principle of adhesion. But the improvement in Mr. Sawyer's process, as we understand it, is not the use simply of an impervious flexible support, but of an impervious flexible support with an elastic surface. He had noticed that a special defect in carbon prints was due to the strain between a surface like that of carbon tissue, expanding when wet, and the unyielding, unelastic surface of glass, zinc, and other rigid supports: hence he felt that if the support to which the tissue was attached could be made as elastic as the tissue itself, and at the same time retain its impervious quality, a great gain in the delicacy of the print would be secured; and his patent transfer paper appears to meet all the wants of the case. All genuinely interested in the progress of photography must hail with satisfaction every step which simplifies the production, and increases the beauty, of the only class of prints of which, up to the present moment, it was impossible to say that they are really permanent, and we congratulate Mr. Sawyer on his valuable contribution to the value of the carbon process.

DEVELOPING BROMIDE PLATES.

As the Photographic Section of the American Institute, Mr. D. C. Chapman described a method of developing bromide plates which, so far as he knew, was novel. It was, however, in point of fact, the method which Col. Wortley and Captain Abney have used for some time for emulsion and other dry plates, and which we have more than once published. It may be interesting to give Mr. Chapman's statement as it appears in Anthony's Bulletin. Mr. Chapman, addressing the meeting, said:—

"In making some experiments in dry plates I have fallen upon something which I think is new. It is new to me, at any rate. These are bromide plates: not emulsion, but dry plates. They are made with a Morrison lens, thirty seconds' exposure, and they are all that I could ask for as negatives. I was trying some regular bath plates, developing with silver and pyro, and I had one of these bromide plates in my hand, and did not notice it until after the picture was developed. I was surprised to find that I could develop a bromide plate without any iodide in it with acid pyro and silver, after the first details are brought out by an
alkaline development. I repeated the experiment, and found that I could make a picture in much less time with no danger of fogging, and perfectly clear in the shadows. In these plates the first details were brought out faintly with a strong alkaline solution. If that alkaline solution had been diluted the plate it would have caused the image all over; but the details came out readily under that strength of developer. The plate was then washed, and the high lights were just as intense as the shadows, and no more so. It was then treated with a little citric acid, to neutralise the ammonia solution, and strengthened up with pyrogallic acid, tannin, and citric acid; the ordinary developing solution. It intensified as readily and quickly as an iodide plate, and in future, with my bromine plate, use that development.

"The great advantage is, that you can use a very strong alkaline developer to start your image, and then there is no danger of fogging afterwards, if you use acid silver to strengthen up the faint image on the plate. You get no pinholes, and the image is perfectly clear in the shadows, and easy to work on. All that must be done hereafter is to wash it with normal solutions of pyrogallic acid, tannin, and silver."

"I have tried Stillman's developer, in which he used liquid ammonia. My experience with the ammonia is, that it has more tendency to fog. For my standard developer I take twenty grains of carbonate of ammonia, one grain of bromide of potassium, and one ounce of water; that I keep as a stock solution. Take a grain and a half to the ounce of pyrogallic acid—that is the solution for developing—flow that on the plate until you cover it, say, half an ounce. Flow over the plate or two or three times after it has been washed with water. Then add three drops of the alkaline solution to that, and flow over the plate again, and the image will appear very quickly. This alkaline developer is left on only long enough to show the image by reflected light, and then the plate is washed quickly, and flowed with a second grain solution of pyrogallic acid, to neutralize the ammonia that may be left in the film. Then re-develop with pyrogallic acid, tannin, and silver. It strengthens up very readily; perhaps in a minute the whole thing is done."

**RECENT ADVANCES IN PHOTOGRAPHIC SCIENCE.**

**BY JOHN SPILLER, F.C.S.**

In this room, on the 20th January, 1853, the Photographic Society of London was founded, after a very successful exhibition of photographs had been held under the auspices of the Society of Arts. The then new collodion process, invented by Frederick Scott Archer, had given a great impetus to the study of photography, and was already being widely practised by amateurs, who sought in the newly-formed Society the means of interchanging experiences and discussing their results. Helped by Royal patronage liberally bestowed, and by the zealous working of its early members, the art was soon made commode advances, and the Journal of the Photographic Society for the next following years may be consulted as the sole record in England of a history which has in latter times borne fruit since has rarely been equalled or excelled in other departments of applied science. For some of these improvements, and especially those of recent date, it will be unwise on my part to dispute your attention; taking, as far as time allows, merely an immediate cognisance of those principles and processes which have served to popularise photography in the present day.

In this effort, let me begin by acknowledging my indebtedness to many friends who have kindly aided me by sending specimens illustrating several of the newest phases of the art. Some of these photographs are shown as notes and examples of high artistic value, including portraits, landscapes, "combination prints," enlargements, and transparencies; other specimens are either of historical interest, or shown as illustrative examples of particular processes. The programme being somewhat wide for the limits of one lecture, I must hasten to approach my subject under appropriate headings.

**Collodion Processes.**—Beyond the general recognition of liberal proportions of bromides and more alcohol than formerly used, the composition of photographic collodion cannot be said to have been altered from the practice of former years. Cadmium salts are now in general use as "sensitizers," and more attention is paid to the quality of pyroxylene (or nitro-cellulose) employed, some operators preferring that made from paper, according to the recommendation of Dr. Lawes and Ladd, and others that the "emulsion processes" are gaining ground from the fact of their enabling us to dispense with the "nitrate bath," the collodion-bromide process of Messrs. Sayce and Bolton leading the way to this improvement. This admirable suggestion is founded upon an earlier observation made by Mr. G. Wharton Simpson, who used a collodion-chloride emulsion for coating paper to be used in the printing process: the leading fact being that chloride (or bromide) of silver may be produced in collodion by double decomposition, so as to furnish a product containing at once all the ingredients ready for immediate use—whether in camera or printing-frame—and which may be kept for lengthened periods without sensible deterioration; since the haloid salt is formed in so finely divided a state that its rapidness is a decided advantage. Lieut-Colonel H. Stuart Wortley advocates the introduction of nitrate of uranium together with the silver, and has published formulae which are even now on their trial, the advantages claimed being greater sensitiveness combined with special superiority in rendering colour—an effort which Dr. Hermann Vogel believes he has equally successfully attained.

For "dry plates" possessing permanent sensitiveness, the writer claims to have led the way by publishing in 1854, in conjunction with Mr. Crookes, the first dry-plate process; and although the nitrate of magnesium is no longer employed for this purpose, the possibility of the case was established, and a host of other "preservatives," including the collodion-albumen and gum-gallic processes, are of daily use, and the latest development of the art being the albumen and beer process of Capt. Abney, R.E., which has done such good service in securing photographs of the recent transit of Venus.

**Collodion Transparencies and Enlargements.**—Collodion-chloride of silver has been used very successfully by Dr. Van Monckhoven for copying and enlargements, and her Majesty's War Department makes good use of the same process for reproductions. As a method of copying faded photographic prints this plan of working has been shown by Mr. H. Baden Prichard to offer great advantages. Mr. James Hughes, of Ryde, produces "transfer collodion enlargements" by development upon glass, and subsequent transference of the toned collodion film to a sheet of white paper or cardboard, by which excellent results are secured, the permanence of the finished work being in no case impaired by the unalterable nature of the materials employed. A similar principle is made use of in the production of photo-enamels, the film being transferred in these cases to surfaces of porcelain or enamelled copper, and subsequently fired. Several operators have brought this process to a state of perfection, and the permanence of these photo-enamels is beyond question.

Mr. Valentine Blanchard has within the last few days described a process of enlargement in which albumenized paper is employed for the production of paper negatives with promise of great results. Mr. Edwards has recently shown some good enlargements, and Messrs. Spencer, Sawyer, Bird, and Co. use the autotype process for the same purpose, where the generally admitted delicacy of
the carbon print is taken advantage of both in securing the intermediate negative, or "transparency," and finished print. The details of this process will be again alluded to under the head of carbon printing. The Woodburytype impression delivered upon glass also furnishes excellent transparencies; but none of these processes give better results than the simple collodion when properly toned, as many of the capital lantern slides of Mr. Frederick York, and the excellent enlarged transparency of the full moon which our worthy Chairman gave me in 1860 as an average sample of his work.

Silver Prints.—The charge of want of permanence brought against the ordinary photographs printed upon paper prepared with the chloride and nitrate of silver is sustained by a mass of evidence, and the fading action is observed to be closely connected with the use of hypophosphites as fixing agents. Much can be done by careful manipulation and by paying great attention to chemical conditions, in the way of overcoming, or reducing to a minimum, the destructive action of sulphur compounds upon the silver which forms the basis of the photograph; foremost amongst needful precautions may be mentioned the use of ammonia or carbolic acid to maintain the fixative to the last moment of the fixing bath, and this followed by a most careful washing, completed with at least one immersion in hot water. Silver prints subjected to this treatment are to a great extent protected against the chance of fading, especially if preserved in a moderately dry atmosphere or closed portfolios; but there is yet another cause for suspicion whenever the solvent has been used for the purpose of imparting a glossy surface to the paper. White of egg is known to contain a certain proportion of sulphur naturally combined with the organic elements, and whenever the albumen undergoes decomposition this sulphur is either in part liberated, or free to act upon the silver. We do not know at present of any sure method of counteracting this evil, but it might be worth while ascertaining how far tannin or carbolic acid, applied in the final stage, renders such organic changes impossible.

Mounting materials and the cardboard itself have often to be tested for impurities, the presence of which may defeat all our previous efforts towards securing the permanence of the silver print, however well it may have been toned, fixed, and washed.

Printing in Carbon or Pigments.—For the reasons just now stated it has become imperative to seek for other means of securing a finish, dispensing altogether with silver and sulphur, may escape the possible contingencies for the old process is liable. Uranium printing offers a better chance of permanence, but although experiments have from time to time been made in this direction, the evidence is not yet sufficiently conclusive to warrant an absolute reliance being placed in this mode of working. The necessity for appealing to a chemical process involving the use of a costly metal appears, however, to be mainly disposed of by the fact that so much progress has lately been made in carbon-printing that improvements seem for the present to arise out of the mastering of its details. So far as I am aware there is no instance on record of a faded carbon print, and there is a reasonable ground for believing in the permanence of combinations of gelatine and chromic oxide, which form, as it were, the cementing materials around the particles of carbon (or pigment) composing the gradated shades of the picture. The chemistry of carbon printing is perhaps not yet fully made out, but it has received much attention from Mr. J. W. Swan and others, who have helped forward its practical realization. We all know how unalterable is a sheet of parchment, and yet this is but an untanned film of animal gelatine. It dissolves slowly in boiling water, but resists attack from the ordinary oxidising influences of the atmosphere. Properly tanned, or indurated with certain metallic salts, it becomes insoluble, and even more indestructible. Indian ink, Frankfort black, and other forms of carbon (including black lead, used in some experiments by M. Marion) may certainly be depended upon for permanence, and so also may chromic oxide, which for years past has been employed as a pigment. The only question that arises in my mind is that we might perhaps "make assurance doubly sure" by resorting to an after-tinning process as I pointed out five years ago. Let alum and the metallic ingredients do their work as now, and finish in a bath of tannin or other astringent.

Having thus reviewed the chemical question, we must descend to practical details, and learn how a carbon print or "autotype" is usually produced. This I am enabled to place before my hearers with all the advantages of latest improvements, inasmuch as an admirable summary of all that is known upon the subject has just been communicated to the Photographic Society by Mr. J. R. Sawyer, in a paper entitled "Photography in Permanent Pigments, with Recent Improvements in Autotype Transfer."

Mungo Ponton having shown that paper coated with potassium bichromate is affected by light, and Becquerel that the presence of gum or gelatine hastened the change, Poitier conceived the happy idea of introducing a pigment which, by becoming locked up in the altered gelatine tissue, rendered it possible to obtain a carbon print. This end was secured merely by washing with water to remove the unaffected portions of the chromated surface, leaving insoluble those parts, in gradation, according to the greater or less marked action of the light. Mr. William Blair, on the other hand, having improved the process by directing his operations to the back of the positive coating, producing superior results as regards the rendering of half tones, but necessarily obtaining reversed pictures. Mr. J. W. Swan, of Newcastle, greatly improved the process by introducing a system of transfer in which india-rubber paste was employed to turn over the image, and it could be developed with greater certainty by washing in warm water after transferring the picture to an appropriate mount. Mr. J. R. Johnson proposed the use of a rigid temporary support, such as a plate of zinc or glass, to receive the pigmented gelatine film and hold it during the process of washing. By employing reversed negatives Mr. Johnson was enabled by "single transfer" to mount the carbon print on a sheet of aluminised green paper.

Such was the state of the process when Mr. J. R. Sawyer observed that he could obtain much finer results by discarding the rigid supo and, returning to paper specially prepared, which, permitting of extension and contraction during the washing and subsequent drying of the carbon print, or autotype, was not so apt to break the fine lines. Mr. Sawyer's patent "flexible support" is paper treated first with chroine alum and gelatine and allowed to dry; such a coating is insoluble in water, as Mr. Swan had previously shown. Upon this a layer of ordinary gelatine (5 to 10 per cent.) is applied, and this is coated with a solution made in a digester, as follows:—

<table>
<thead>
<tr>
<th>Ingredient</th>
<th>Quantity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Button, or bleached lac</td>
<td>1 lb</td>
</tr>
<tr>
<td>Water</td>
<td>5 quarts</td>
</tr>
<tr>
<td>Borax</td>
<td>4 ounces</td>
</tr>
<tr>
<td>Soda crystals</td>
<td>1 ounce</td>
</tr>
</tbody>
</table>

In order to get a perfectly smooth surface, the paper is subjected to rolling pressure between metal plates, and each sheet at the time of use is rubbed over with resin and turpentine mixed with a little wax. It is not difficult to imagine that a "flexible support," built up in this manner, would act as a soft couche or bed, for the reception of a carbon or pigment print about to be developed, and we readily believe that superior results can be obtained in this way. The final result is transferred to sheets of paper coated with an emulsion of gelatine and

Journal of the Photographic Society, October, 1869, p. 109.
precipitated sulphate of baryum, mixed with a little chrome alum.

As the temporary support can be used repeatedly if again rubbed over with the repellant coating of wax and resin, the cost is no bar to its employment, and the process is said to be admirably adapted for amateurs' use. If these bright anticipations are realized, we may shortly hope that carbon will replace silver for all ordinary purposes, and that no more complaints will be heard of fading photographs.

(To be continued.)

PHOTOGRAPHY IN THE PARIS PRISONS.*

It is now some time since the Paris Police availed itself of the aid of photography in securing pictures of those who come under its notice, and there are now two young and skilful operators engaged by the Prefet de Police for fulfilling duties of this kind. The routine labours they have to perform have in no way dampened the ardour and energy of these gentlemen, who are to be congratulated on the results already attained under their auspices.

Criminal photography—which made its début under very modest circumstances, and which is now carried on in Paris in a manner scarcely favourable to its full development, the rooms and studio being established behind barred windows on the upper floors of some houses—has, however, been called to fulfil, for the staff, besides satisfying the wants of the various Police Stations, the House of Detention, Masses, Saint Lazare, and other prisons, undertakes the portraiture also of subjects in the Morgue.

Those who are acquainted with the aspect of Paris prisons—with the House of Detention, for instance, which is a veritable well, daylight only entering from above—will understand that general apparatus and especially rapid lenses are necessary in the case of criminal photography; and as a fact, we may mention that all the parapetmaphia, aplana
tic and rapid lenses are French, and bear a name which of itself is sufficient guarantee of the quality of the articles.

We must also render homage to the skill of the operators, who, under the most unfavourable conditions, know how to obtain with rapidity the most excellent results, not only from a likeness point of view, but as artistic productions. The photographers of the Prefecture have the rank of inspectors, and the authorities can rely upon their discretion in all matters that come under their notice. The division of labour is pretty nearly the same as in private establishments; only retouching, which is often abused in our best studios, is here almost entirely suppressed, for it is the work reserved for anything. The portraits, however, receive much oare in cataloguing and describing, every one having attached to it particulars respecting antecedents, &c., which are drawn up with scrupulous exactness. The advantage of having a portrait of this kind, whether for establishing the identity of an individual who refuses to give up his name, or for arresting or even for the police, must be obvious to all. By merely examining the copy of a portrait of any individual whom it is desired to find, and distributing the pictures among police-officers and detectives, you naturally enough multiply the chances of finding him.

All prisoners are not photographed, however, for this would be too long a business, and in many instances quite useless. Such a proceeding would, indeed, be abusing the art, although, no doubt, the authorities have a perfect right to secure a picture of all prisoners. Every dangerous or habitual criminal, or person likely to be one, is, however, photographed, and thus all the habitudes of the prisons are included in the police albums. Some of these characters have been honoured by having two portraits taken, one in profile, and one full face, so that there is little chance of their escaping recognition afterwards.

The reproduction of photographs already in existence is a branch of duty which the police photographers do not overlook, in case they already possess a picture of the person "wanted" which has been obtained from a friend or accomplice.

An illustrated journal recently gave a sketch of a fancy nature, representing a rebellious criminal held down by main force in front of a camera; unable to stir from the spot, the model is depicted meeting every grimace and contortion possible, and thus he contrives to prevent a natural photograph being taken, which might compromise him hereafter. Such an incident as this never took place in prison, although it may happen often enough that the model does not take kindly to the photographer. But it would be little good a prisoner resisting, for the authorities know very well how to treat refractory patients.

The operation of posing, however, far from being disliked by a prisoner, is often looked upon by him as a treat, for during the quarter of an hour that he is out of his cell, he enjoys a little pure air and daylight, which represents a souvenir or tasteful of liberty. Many, indeed, pose themselves with a degree of coquetry that is perfectly surprising. It is, in fact, scarcely credible that in the courtyard of the House of Detention, a degree less lively than the Valley of the Shadow of Death, the most of all to rob and assassinate of both sexes, often clad in the vilest rags, should strive to get themselves taken in a graceful position, covering what corporal imperfections they may possess, the results of intemperance, accident, or punishment, and making quite an unparalleled display of vanity. After the House of Detention, the prisons of Masses and Saint Lazare form the most work for the photographers of the Prefecture, and then comes the Morgue, where also a dark room and laboratory are provided.

It is easy to understand the importance of photographing subjects in the Morgue, whether the pictures aid friends in discovering the body, or, after interment of the deceased, indicate where the various bodies have been buried, so that it is some satisfaction to acquaintances who identify the body too late, that they are informed of the resting place of the unfortunate. Many questions of a delicate and confidential nature, which need not be made public, are in this way solved without unnecessary pain to relatives.

Besides criminals and the victims of the Morgue, there is a third class which the police photographers occupy themselves with. There are many indigent strangers wandering about the streets, and whose friends at home have to be communicated with. Portraits obviate a great deal of unnecessary expense and trouble. Finally, it is contemplated to photograph the scene of any crime or accident, and such pictures will be added to the instructions given to the prosecutor, who will thus be enabled to supply the jury with much more accurate details of a crime than he would otherwise be in a position to give.

The results already prepared by the police photographers are thoroughly appreciated by the authorities; the portraits of guilty parties and of victims, which have been prepared, have very much facilitated the administration of justice, and the fidelity with which letters, plans, signatures, and documents of all kinds have been copied by photography is invaluable on many occasions. Sometimes application is made by foreign governments for copies of documents and portraits, for the purpose of pursuing a criminal, and in this case it is rare that the French authorities refuse to give their assistance.

In a word, whether it is question of a murder, a fire, a robbery, forgery, or other crimes, political or not, photography comes to the aid of the judge, as it does to the humble policeman. At one time despised, the art to-day fosters itself upon public attention; and such is its importance, that it will rapidly come to be one of the best safeguards against crime, seeing that none can escape its crucial observation.

*Moniteur de la Photographie.
NOTE ON CARBON PRINTING.

BY M. GRAND.

I do not suppose I am the only one who has found that if a carbon image developed upon a provisional support is attached to its final basis while still swollen with water, it loses much of its delicate character. It is essential that the image should be quite dry before it is separated from the provisional support. For this reason I have been compelled to reject stearine paper as a support, because I find that the pellicle forming the image becomes detached as soon as the latter dries. Many other supports hold the dry image firmly, and only allow of its removal when alcohol, benzole, and other appropriate solvents are employed; but all of them seem to demand great care in development, especially when the prints are of large size, for otherwise the thicker parts of the picture will be found to leave the support.

I have employed, with much success, as a provisional support for developing a carbon image, paper which has been treated with caseine, the latter being dissolved in dilute ammonia, into which the paper is dipped, being afterwards immersed in an alum bath. Under the influence of the small quantity of ammonia retained by the dry caseine, the latter absorbs some alumina, which renders the caseine perfectly insoluble and impermeable. The carbon tissue is applied under water to this support, and pressed for some minutes with blotting-paper. On development, the image adheres with such force to the caseine that it may be handled and treated as roughly as a good silver print.

The image washed, aluminized, and dried, is applied (still under water) against the definite support, which should be faced with gelatine and pressed with blotting-paper. To separate the two papers, it is only necessary to plunge them when dry into ammonia diluted to ten times its volume of water; they are gently moved to and fro, and at the end of a few minutes the caseine dissolving, the two papers separate of themselves, or, at any rate, with very little resistance, exactly as in the first operation of development. The dry image is pure and brilliant, and preserves all its delicacy and half tones.

The advantage of operating in this way consists, above all, in the great adherence of two soluble bodies in aqueous liquids, which is much more powerful than between a soluble body in water, and another body soluble only in a combustible liquid, such as alcohol or benzene.

The solution of caseine for facing the paper should be as viscous as possible, to give the paper the brilliancy of an albumenized material. The caseine should be freed from all gready globules, and one litre of milk will furnish as much as one hundred and fifty grammes of caseine.

The paper treated with this material is most excellent as the definite support for the image, in case the operator is working with a reversed negative; and I am convinced that any photographer making trial of it in carbon printing will abandon other methods which may be more familiar to him, and which may yield passable results.

I may observe further, that dilute, and even concentrated ammonia, has absolutely no action upon the image, or upon the gelatine in the sizing of the paper.

In reference to this last remark of M. Grand, M. Chardon is of opinion that ammonia has not that innoxious character claimed for it above. According to his experience, ammonia, when contained in water in the proportion of only five per cent., under ordinary circumstances, attacks and destroys the sizing of paper.

Correspondence.

ENLARGED PAPERS NEGATIVES.

My dear sir,—I am sorry I was not present at the meeting of the London Photographic Society last Tuesday, when Mr. Blanchard read his interesting paper. It is very strange that I have been working the same process for the past three years, in proof of which I send by this post a negative that has been done all these years. I am sure that our old friend Mr. Blanchard will not think for a moment that this is sent in an unkind spirit. I thought that it was original on my part, and I have no doubt he did the same. It is a process of great promise, but to work it successfully there are several points that require making clear, or in ordinary hands it would give a great deal of trouble, and that is why many good and beautiful processes lie buried in the photo. literature of the past.

I can reproduce small carte negatives (same size as original), giving capital results, by making a transparency in another manner. It would be too long to go into the whole details of the process here, as I should wish, but at some future time I hope to be able to give the results of my labours fully in the form of a paper at one of the meetings. For an article for the Photographic News—that is, as soon as I can find time; but you are well aware that with a professional photographer time is fully employed.

Trust me that Mr. Blanchard will look upon this note with the true friendly feeling that he always displays at our meetings and social gatherings where I have had the pleasure of making his acquaintance,—I am, dear sir, yours very truly,

Stratford Green, E., April 19th.

W. Brooks.

Proceedings of Societies.

THE SOCIETY OF ARTS.

At a meeting of this Society, held on the evening of Friday last, the 17th inst., Mr. WARREN DE LA RUE, F.R.S., in the chair,

Mr. John Spiller read a paper on "Recent Advances in Photographic Science" (see p. 200), and exhibited a number of fine examples of the new and improved processes of the last few years.

In the course of the conversational discussion which followed, Mr. BLANCHARD, at the request of the Chairman, gave a detailed description of his method of enlargement recently brought before the Photographic Society.

Mr. J. B. Sawyer gave an interesting explanation and demonstration of his modification in the carbon process.

Mr. J. T. Taylor, referring to Dallmeyer, expressed his opinion that it was a typographical rather than a lithographic process, and Mr. W. Noel Hartley pointed out the analogy between the Woodbury process and the method of nature printing employed by Mr. Henry Bradbury some years previously.

Dr. W. J. Russell would like to have heard more definite information about the chemical action of chromate on gelatine under the influence of sunlight. He was inclined to believe that the carbon print was permanent, whereas albumen was one of the worst foundations for a photographic record, since it was so difficult to purify, and always contained sulphur.

The Chairman, in moving a vote of thanks, regarded with satisfaction the present condition and future prospects of the art, and pointed out some of its astronomical and scientific uses.

The vote being duly acknowledged, the proceedings terminated.

Talk in the Studio.

INDIAN MEDALS.—Our readers will learn with pleasure that Mr. William Bedford, son of Mr. Francis Bedford, has received the Viceroy's gold medal at the Bengal Photographic Exhibition for the best landscape.

DILUTE ACETIC ACID BEFORE TONING.—In referring to the common use in America of acetic acid in the washing water for prints prior to toning, a few weeks ago, by a printer's error
ALAN CLARKE.—The yellow spots are due to hypo. They have all the appearance of spots caused by imperfect fixation, in which instance hypo is the cause, and spotting with any fixing material, whether the use of a weak or worn-out fixing bath, or imperfect immersion of the print in a strong fixing bath, will stop the spots. If the spots appeared before fixing, they are due to the print having been brought into contact with hypo before fixing; probably the blotting-paper of which you speak has been contaminated with hypo by some means.

A. B. C.—For general purposes the rapid, beyond a question.

SUBSCRIBER.—So far as your description goes, I think all these pictures you mention are copyright. The presence of photographic copies in the market freely advertised for sale does not in any degree prove or suggest that the pictures are not copyright. In the case in question the right of photographing has been purchased from the owner of the copyright, and hence the photographs are published under the copyright.

R. EVANS.—You will find in our advertising columns the addresses of several gentlemen who undertake to give lessons, from whom, of course, you will be able to obtain particulars of terms, &c., on application.

C. W.—The number you received was forwarded from the publishing offices, though not enclosed in the usual wrapper.

NORTHUMBERLAND.—The marking on the piece of sensitized paper you enclose is caused by the formation of air-bubbles between the paper and the solution. The remedy is to place the paper on the surface of the solution. If you have any reason to fear that a bubble has been formed, the sheets should be raised again instantly, and the bubble replaced on the surface of the bath. Condensed steam from an engine is not always pure, and not safe to use for distilled water in photography.

B. FEATHER.—If this gentleman will forward his address to us, we will furnish it to a former customer, who wishes to communicate with him about a portrait.

J. T. F.—In the first chapter of the "Practical Printer," in which the term soda is used, we explained that it was the American term for common carbonate of soda, used in the households in this country as "washing soda."

T. E. B.—We do not know the addresses of the makers of fans and other fancy mounts for photographs. It is very probable that you will find them advertised in the "Stationer," a monthly journal published by Dean and Son, Johnson's Court, Fleet Street.

Mr. Fray's article on his mode of enlargement appeared some time back.

ROWLAND LEIGH.—Novelties in photographic apparatus are frequently shown at the autumn exhibition of the Photographic Society, but only recent novelties. A few hours spent in visiting the establishments of camera dealers and photographers will afford the best opportunity of seeing various examples of apparatus.

BELL.—Try reducing the exposure considerably, and using a weaker developer of (say) six grains potassium of iron to the ounce, and twenty minims of acetic acid. It is probable that you have been trying new and thin samples of collodion. Very often under such circumstances the solution of a grain of potassium permanganate to each ounce of collodion proves effective. The addition of a trace of gelatine to each ounce of developer often proves useful in such cases. 2. In producing carbon transparencies on glass you will find a preliminary coating of collodion useful.

M. D. L.—The markings on your sensitive paper are what are commonly known as "tear-drops," and arise from drops of the silver solution remaining in isolated spots on the surface of the paper, instead of draining off in a steady stream, and drying evenly. The tendency to this may arise from two causes:—sometimes, but not frequently, from the use of a too strong silver bath; most frequently from the paper having been kept in a very dry place, so that the albumen surface has become hard, taut, and repellant. The remedy consists in avoiding the use of the tube, but when the wet condition is reached, and the paper is drying, they may be removed by blotting-paper.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

PHOTOGRAPHY FOR PHYSICIANS—GERMAN PHOTOGRAPHIC LITERATURE—TOUGH GLASS.

Photography for Physicians.—There is nothing new in being able to photograph the invisible, for it has long been known that the photographic lens perceives much that is passed over by the human eye. In the violet end of the spectrum, for instance, there are lines and double lines whose existence was discovered by spectroscopic examination until photographers came and fitted a camera to the eye-piece of the instrument, and thus secured a record of things which previously were not known to exist. Until Dr. Vogel made known his discovery last year, it was thought, too, that there were some lines of the spectrum visible to the eye and invisible to the camera; but this appears not to be the case, for so long as a suitable collodion plate is employed, any of the lines of the spectrum may be reproduced, whether they are in the province of the violets or the orange. A little while ago we called attention to a very useful application of the camera in photographing the invisible which is made use of in Paris at the Bank of France, by M. Gobert, a photographer attached to the establishment. An invention has been made upon cheques, for instance, the quick eye of the lens often discovered the obliterated word, which was quite invisible to the eye, and thus aided in the detection of fraud and robbery. Any one who has copied a cheque which has been enclosed in a letter knows how much more vigorous marks upon it resulting from contact with the writing come out in the copy than they are in the original; indeed, sometimes being made up of yellow ink, printed off from a letter in the copy, but not in the original. Those who occupy themselves with photolithography, or the reproduction of maps and sketches, know, too, how annoying it sometimes is to find big patches over their plate which were altogether invisible upon the original, a closer investigation showing a rougher texture. Now we learn that even the smallest under ordinary circumstances, escape notice. It is now suggested, by Dr. Vogel, we believe, that physicians might employ photography with advantage for the purpose of forming a diagnosis of a case, for if we are to believe some statements which have recently been made, the art would aid the medical man considerably in coming to a decision. Thus a circumstance is mentioned of a woman who, though her face was not free from any eruption, the negative showed spots all over the face, and within a day or two the model was found to be suffering from a severe attack of small-pox. Now if the camera can perceive these spots before the eye discerns them, it is obvious that a photographic plate may at times be an important assistance to medical science, as it has been for many other of the sciences already. In registering the different forms of disease and illustrating characteristics thereof, the camera is already freely used by medical men, and it will only be necessary to call their attention to this new method of employing it to ensure a trial of its capabilities in this direction. For the purposes of medical instruction at schools and colleges photographic diagraphs are now largely used, the preparations being enlarged under the micro-camera, and then further amplified in a lantern. In this way a good deal of microscopic work may be avoided, and a demonstration can be made much clearer than when the student does not enjoy the benefit of the professor's assistance when looking through the microscope. The medical profession are therefore faced with the new science of photography, and it is by no means impossible that a camera, or adaptation of it of some kind, may in a little while be deemed as important a medical instrument as the stethoscope of the present day.

German Photographic Literature.—Germany is to have a weekly photographic journal, and the first number of the new paper is now in our hands, dated April 3rd, 1875. Its title is the Photographisches Wochen-Blatt, and the editor is Karl Schrider, of Weimar, who for some time assisted Dr. Vogel in his photographic laboratory at Berlin, and who was one of the chief photographers attached to the Prussian staff before Strasbourg and Paris during the recent Franco-German war. It is impossible to judge of the merits of the new journal from the first number, but it is matter for surprise that so extensive a country as the Waterland, should not have possessed a weekly journal before this. However, from the circumstance that both Helios of Dresden, and Lich of Berlin, came to an abrupt end last year, one cannot say much in favour of the prospects of photographic literature just now, and we believe that the only two periodicals in North Germany at present are the Mittheilungen of Berlin, and the Archive of Elsbfeld. In South Germany there are also two, the Correspondenz and the Notizen. The Wochen-Blatt does not profess to be the organ of any society, but will maintain an independent footing, and although its editor resides at Weimar, the paper will be published in Berlin.

Tough Glass.—The important invention of rendering glass tough is attracting attention everywhere, for brittleness has hitherto been the main drawback which has prevented the use of the material in many ways. Glass has so many qualities to recommend it for use: it is transparent, scarcely ever attacked by chemicals, has no corroding action upon other substances, and is capable of being moulded into any shape, it is agreeable and cleanly material. The new tough glass is not, however, faultless; it cannot be worked into shapes, neither can it be bored or ground any more than a diamond; so that if it were desired to have photographic plates of the material, those would have to be made the proper size at first, for they could not be cut or fashioned after the glass has been toughened. As regards its appearance, the tough glass is not to be distinguished from ordinary glass, for it is just as transparent and pure as the ordinary material. The method of toughening appears to be a secret, and takes place during the cooling of the material. It is said that the inventor has demanded a sum equal to one franc per head upon the whole population of France for the process, which would amount to the respectable sum of forty million francs; but this demand is altogether too exorbitant. Many chemists are engaged in experimenting in order to find out the key to the problem, and Professor Bauer, of Vienna, seems to be in a fair way of discovering the secret, having already produced a hardened glass which is not brittle, and which will withstand a high temperature, Professor Bauer's method of working is to place ordinary glass in a furnace until heated to 500° to 600° Cent., and then to lower the temperature by dipping the mass into hot paraffin, so that the glass shows a temperature of 400° C. Subsequently the mass is gradually allowed to cool down to 40°.

RECENT ADVANCES IN PHOTOGRAPHIC SCIENCE.

BY JOHN SPIELER, F.C.S.*

Photography in the Printing Press.—Of late years great advances have been made in this interesting department of photographic printing, and there are now distinct principles of working, which under varying circumstances are capable of meeting the object in view. The reproduction of maps, plans, line engravings, and subjects destitute of half-tone, presents no difficulty whatever, any one of

PHOTOGRAPHY IN PERMANENT PIGMENTS, WITH RECENT IMPROVEMENTS IN AUTOTYPE TRANSFER.

By J. R. SAWYER.

To Mr. J. R. Johnson we are indebted for the invention of a method of double transfer, doing away with the indiarubber coated paper, and which went a very long way towards making the process simple and easily workable. His method is based upon the fact that if two impervious surfaces are pressed into contact, and the air entirely removed from between them, they will adhere, by virtue of atmospheric pressure, without the necessity of using any cement or adhesive material at all. Here we have a distinctly new principle, which Mr. Johnson applied as follows:—The pigmented tissue being printed, it was immersed in water, and when it had become just limp was laid down upon a plate of metal, glass, slate, or other impervious body. This was called the rigid temporary support. The air and water were pressed from between these two surfaces by means of a sort of india-rubber edge fixed into wood, and known as a squeegee. The two surfaces so forced into contact were allowed to remain for a few minutes, then placed in the hot water, which, dissolving the layer of soluble gelatine immediately in contact with the paper, allowed the paper to be stripped away, the back of the

THE PHOTOGRAPHIC NEWS. [April 30, 1875.

the photo-lithographic processes lending itself to this purpose, and invariably producing satisfactory results. Mr. Butter, of Woolwich Arsenal, has executed a large series of plates illustrating military equipment. Mr. Griggs has done some admirable work for the India Office, including patterns of Cashmere shawls, &c., involving the use of colours. Major-General Sir Henry James and the Topographical Department at Southampton, working by a modification called photo-sinography, are reproducing the Ordnance maps; and the Chatham establishment is doing very similar work by a process devised by Captain Angus and Mr. Papyrus. The Dallastyle, Kerography of W. J. Linton, the Electro-Photography of Chas. Hancock, probably come into this division, but no details of these processes have ever been published, although the results in some instances have been highly satisfactory.

The simplest form of photo-lithography is that in which a sheet of paper prepared with gelatine and chromate is exposed to light under a negative, next uniformly coated with a thin layer of litho ink supplied from the ordinary inking-roller, then submitted to the action of warm gum-water to loosen the attachment of the unaltered gelatine, and with it the superimposed greasy ink, which, washed away, leaves a transfer ready to be laid down upon the lithographic stone. Great care is requisite to prevent abrasion and injury to the design in the process of developing the transfer; but, at this point attended to, it is manifest that the ink adheres permanently only to those portions which have been hardened and rendered insoluble by the action of light, and these are in turn transferred to give the design upon the stone.

Another class of processes includes those employing a layer of gelatine, which, by the action of light, exhibits a different rate of water-absorption according to the depth or extent of the indurating action induced by the solar exposure, and in these we have true gradations of tone.

The first in this category was Paul Pretsch's photo-galanography, which, aided by the encouragement and assistance of the Chemist and Publisher, Dr. Hugo Muller, certainly paved the way for greater results. Pretsch's first English patent is dated November 9th, 1854; he described his process here in April, 1856, and specimen prints were afterwards issued with Nos. 89 and 103 of the Photographic Journal. Mr. R. H. Courtney's process of later date is very similar.† The general principle was to expose a thin film of chromated gelatine (under the negative) for just such a period of time as would just bring out clearly the effect of relief when afterwards sponged with water. A cast was taken in gutta-percha or plaster of Paris of the whole surface, which exhibited depressions corresponding to the intensity of light-action, and then from this cast an electrolyte was made which could be printed from like any ordinary surface block.

Omitting the successive steps in the history of photo-mechanical printing, we come now to the latest examples of work in this class as exhibited in the Albertype, and the collographic process of Messrs. Spencer, Sawyer, Bird, and Co. A grand step in the way of progress was presented in 1869, by Herr Joseph Albert, of Munich, whose invention was rewarded a year later by the Photographic Society of London. In these specimens the gradation in tone is perfect, and we know that an immense number of impressions may be printed from the same plate without appreciable loss of delicacy. The mode of proceeding is somewhat as follows:—A thick glass plate is levelled and floated with a liberal supply of chromated gelatine, which when set is exposed to light under a negative; the upper surface is then acted upon by water and an antiseptic to give at once a printing block. By the judicious use of gum-resins a certain quality or texture known as "slippee" is imparted to the surface, and the ink applied with a roller for each impression. The "Utrecht Paletter" reproduced for the Paleographical Society, coins in the national collections (Numismatist), Thomason's "China" (4 vols.), and Mundy's "New Zealand" may be quoted as examples of recent work executed by the English firm already mentioned; whilst a kindred process, the Heliotype, has served to illustrate Mr. Plimsoll's work, "Our Seamen; an Appeal."

Woodburytype.—Having had the privilege of bringing the first specimens of this process to the notice of the members of the photographic artists, I am under the impression, the Photographic Society, of the R.I.A., 1887, I felt a great interest in inspecting last week some of the most recent examples of the Woodbury process, and for a certain class of work where rapid production is imperative the results leave little to be desired. Mr. Downey's portraits of H.I.M. the Shah were published by thousands within a week of the negatives being taken, and the regular appearance of the illustrations in the "Figaro Programme" (weekly), and the "London Sketch Book" (monthly), attest to the practical success of the process. The details are now so well-known that a brief description suffices. Mr. Woodbury works the chromated gelatine for the purpose of obtaining a hard insoluble film on development, which he terms "gelatine relief." With this plain type metal is cast by action of an enormous hydraulic pressure, which, singular to relate, does not crack the matrix. The mould or printing block thus produced is then served with a warm gelatinous ink, the paper laid on the top, and the excess of pigment squeezed out, which leaves the desired impression, requiring only to be fixed in an alum bath.

The gelatine relief gives admirable casts in plaster of Paris, which forms a pleasing mode of reproducing microscopic objects, and these also were shown at Dundee, but as yet little practical use seems to have been made of the idea.

In conclusion, I must ask your indulgence for many shortcomings in this attempt to bring a very large subject within the scope of a single lecture, and I beg to refer you to Mr. Henry Blackburn's "Handbook of the Pigments," and "The Art of Popular Illustration," Journal of the Society of Arts, March 19th.

† See "Photographic News," Nov. 30, 1874.
picture consequently exposed, and the conditions for successful development fulfilled.

The problem of how to produce permanent photographs with ease seemed now to have received a satisfactory solution. The operations were not difficult, they required no costly apparatus, the materials employed were not expensive. Why, then, did not this improvement at once give rise to a vast development in the direction of permanent photography? Mr. Johnson had, it is true, patented his invention; but it had been patented after the discovery had been come;—the only conditions being that the tissue and material used should be purchased of the company formed to prosecute the enterprise.

In Autotype printing the standard of excellence to be attained has been the exquisite though fleeting beauty of a silver print. These productions are eminently beautiful; the toning with compounds of the precious metals gives a variety of rich, beautiful colouring. The paper upon which the photograph is printed is of a very fine quality, and the finished picture is susceptible of a very high glass and finish. It is not improbable that, for small pictures, Autotypes made by this process of double transfer did not present that delicacy and finish which would make them acceptable to the connoisseur and to the public.

With large work the reverse was the case. For reproductions of paintings, drawings, sketches, engravings (especially of a large size), this process at once showed its inferiority; for besides the value attaching to these productions by reason of their permanent character, there was an additional element of satisfaction in the fact that they reproduced not only the colour of the original, but in many cases the very material in which the original was worked. Thus the "facsimile" of a drawing in red chalk would be reproduced in a tissue having red chalk for its pigment, and similarly with respect to other colours.

And now another step forward was made. It will be remembered that prints from ordinary negatives appear reversed, and need another transfer to cause them to appear in their correct relation. To save time and trouble, it was considered desirable to reverse the negatives; and in copying pictures, works of art, and those objects to which Autotype printing seemed particularly to lend itself, this was accomplished by means of the reversing-mirror.

This proceeding reduced the number of operations to a minimum, and a great success was at once achieved by those who adopted this method of producing their works.

Printing from reversed negatives is known as the operation of "single transfer," and is conducted as follows:—The only materials required are the pigmented tissue and a paper coated with insoluble gelatine known as "single transfer-paper." When the tissue has been printed under the negative it is immersed in cold water, together with a piece of single transfer-paper rather larger than itself. These are brought into contact under water, lifted out together, laid upon a slab of slate or piece of sheet zinc, and pressed into contact with the squeegee; allowed to remain for a few minutes, then placed in warm water. The soluble gelatine at the back of the picture soon begins to dissolve, releases its support (the paper), which is stripped off and thrown aside. The development is continued, and when coated with paper this is rinsed in water, lifted out of the water, and dried in a few minutes in a weak solution of alum, which indurates the gelatine. It is then rinsed in the cold water, hung up to dry, and when dry is ready to trim and mount.

It is apparent that the operation just described cannot well be more simple; and for small pictures it was found that there was always a more crisp definition and sharpness of line than could be obtained by the transfer from a negative to support. I discovered why this should be the case was the next problem.

It occurred to me that the cause was to be found in the yielding nature of the support upon which the picture was developed—namely, the transfer-paper. It will be remembered that in the process just described the printed tissue and transfer-paper were put into contact in a moist condition, consequently they expanded or contracted together—there was no strain between the two surfaces; but if a limp and yielding surface like wetted tissue is laid upon an absolutely rigid support, such as a plate of zinc or porcelain, is it not likely that there will be a strain set up between the two surfaces by reason of the contraction of the damp tissue, and partly by setting-up? And is it not possible that this be of itself quite sufficient to impair the delicacy and crisp detail of small photographs? Mr. J. R. Johnson had suggested the use of a paper coated with an ammoniacal solution of lac; but dealing, as he did, mostly with large work, he did not insist upon its value as a yielding surface, even if he were aware of the fact. Taking, then, the idea that the superior quality of pictures produced by the single transfer process from reversed negatives was due to the soft and yielding film upon which they were imposed for the purposes of development, I endeavoured to discover if some such basis could not be found for prints from ordinary negatives; the material to be perfectly soft and yielding when wet, to receive the limpid negative or couche; but not to contract or suffer strain during development, and, finally, to give it up easily when the development was completed. After many experiments and repeated failures, I at last hit upon a combination that, after a very long practical trial, seems to answer perfectly: and the ease with which it is manipulated is not the least part of its merit.

This tissue, which I have named "flexible support," and for which I have obtained a patent, is paper treated first with a coating of gelatine, then coated with a solution of chromic alum; this, when dry, is coated with a solution made by dissolving (at a high temperature) lac by means of borax and soda.

The coating of gelatine forms the bed or couche upon which the picture is held during development, the lac being the resisting coating which enables the print to leave the surface when finally transferred. The mode of preparing the flexible support is this:—A solution of gelatine is made of variable strength, according to the quality of surface desired in the finished print: for a print to have a dead or matt surface, I employ about a five per cent. solution, for a more highly glazed surface about 7½ per cent., and for a surface about equal to highly glazed albumenized paper a ten per cent. solution. Paper is drawn on a reel, and passed by means of rollers in a bath of the solution of gelatine. It is then passed upon a carbon-paper-making machine with these solutions, and when dry is cut into sheets and subjected to a pressure of many tons in an hydraulic press. The solution of lac is made by dissolving one pound of gum or bleached lac in five quarts of water, in which has been dissolved four ounces of borax and one ounce of soda: this is put into what is called a digester, and heated until the lac is dissolved; the solution is then filtered, and when cold is ready for use. The gelatinized paper is floated upon this solution in a shallow bath or tray, hung up to dry, and then finally rolled between metal plates in a rolling-press; each sheet is rubbed over with a little of a solution made by dissolving resin in turpentine, and adding thereto a few grains of wax. This was employed by Mr. Johnson to rub his rigid supports, to prevent final adhesion, and I believe, used by Firing in a very early stage of carbon printing. As soon as the spirit has evaporated, the "flexible support" is ready for use.

The mode of using is extremely simple: after the tissue has left the frame, it is plunged into water with a piece of the flexible support a little larger than itself; the two surfaces are brought into contact, and air-bubbles lifted out together, and hung up in the air for a period which may vary from ten minutes to one or two hours, as may suit the convenience of the operator. The adhering sheets are then plunged into warm water
and the paper upon which the tissue was made peels off. The picture is developed, and when finished is slipped into cold water, thence into the alum bath, and after rising is ready for the final transfer.

The material upon which the picture finally rests is paper coated with gelatine containing sulphate of baryta as an emulsion in the solution, and rendered partially insoluble with the addition of albumen. Pieces of the paper are cut to the proper size, and immersed in hot water to soften the gelatine; the picture to be transferred is placed in contact under cold water, the two are lifted out together, hung up to dry, and when dry the finished leaves its temporary support with the greatest ease.

The temporary support may be used repeatedly, by rubbing it up with Hill’s Peptole. In the process of the removal of the resin and wax, and will last a very long time. I hope to convince you by practical demonstration that the process is very simple, very easy, not liable to failure, and that the results are such as will bear comparison with the best work of the silver printer; whilst if I can convince you that these productions are “things of beauty,” I can assure you they will be “joys for ever.”

THE PRACTICAL PRINTER IN AMERICA. XXII.

Artistic Toning.

As a rule, in toning the prints, the following will, as a general thing, answer admirably: “tone the prints just as you wish them to be when done.” Looking over a journal one day, I noticed an article headed “Artistic Toning,” and upon reading it I learned several things about toning, and one little clause was the one above quoted. This clause seemed to me to be very important to the young printer, and I wondered at the time why I had never been told that, and I immediately knew, upon reading the above clause, that I could tone, and so I determined to tone a batch of prints as soon as possible, and one rainy afternoon, when the printer did not appear after he went to dinner, I resolved to do the toning myself without saying a word to the employer about it. So I made the bath as I had seen the printer make it a score of times before, warmed it slightly, let stand a few minutes, got, washed, and acidified the prints, washed again, and then commenced to tone them, toning three at a time, and as there were on duty to be toned, being as that had been printed on account of the darkness of the day and the scarcity of the negatives, I did not doubt but what I could tone and fix them all without help. This was the first batch of prints that I ever had the complete management of the toning and fixing of, and I determined to let Mr. L., the employer, and Mr. B., the printer, know that I could tone. With anxious eyes I watched the first batch of prints—in fact, I glared at them—and when they arrived at that stage at which I wished them to be when finished, I took them out and set them to washing in running water. When my next batch of prints was almost toned, I placed in the bath a print that was not toned, and compared the two, upon doing which I found that I could tone much better. I toned them all finally, fixed them all, and one evening when it was raining, I took them through, the “bone” happened to think that there was “no toner upstairs” (so he expressed it, as I afterwards found out), and he came rushing up where I was to tone the prints before it got much darker, for the weather was lowering, and it was getting dark pretty fast. I told him that I had toned, and he expressed his surprise, and inquired, “Are any of them good?” a question which I did not think very complimentary. I assure you. I told him that I thought quite a number of them were good, and when he, upon looking at them, told me that they were “very nice indeed,” I felt bigger at the time than I ever have since. I asked the printer, Mr. B., the next morning how the prints were toned, and he said, “Very well, only they were toned a little uneven,” and upon his showing me what he meant, I determined, as a natural consequence, to do better next time. That little clause led me on, in time, to do the toning in that and other establishments, and made more for the reason of showing a young beginner what he can do by a little reading of how another beginner did, has led me to write this short sketch of my first attempt at toning.

From the above, you who take the first step in toning, or to tone a batch of prints, would give the impression to the beginner that it was a question of so many minutes, as it is in fixing prints, consequently I have here taken special pains to contradict this erroneous thought, so as to prevent the novice from beginning wrongly, as he would be apt to do if he was in a place where the printer or printers would not take any pains to show him, but would be contented on the hurry to get the work done.

Now, since you are to tone the prints as you wish them to look when finished, let us see if you have the right idea in your mind as to how they should look when toned.

You should not wish to have them what may be called “red tones”—i.e., to have the background, draperies, hair, and the face as red as a brick, or, in fact, anywhere near it. You should not tone them so that the draperies and shadow box look blue. You should tone them until the red is just slightly blue, and then the prints should be taken out, even if the rest of the printed paper is quite red. With some baths—especially such ones as the “acetate of soda,” and the bath described last in the preceding chapter—this can be done very easily and successfully; but there are some baths, as the citric acid, chloride of lime, &c., that this treatment cannot be used so well, and in the case of the “citric acid toning bath” the shadows also will have to be regarded, else the whole print will be as red as a brick.

But a little experience in toning with any one bath will give you an idea as to how far you should tone before you discontinue the operation and set the prints to washing. You may say that which I have just written will conflict with the rule given above, but it does not; for the only rule is this: only that part of the print which should be red with another one, when the proper state has arrived, the prints should immediately be removed, and should not be allowed to remain in the bath until the tone has reached the more decided stage. In baths containing either the acetate or the chloride of sodium, or both, in their composition, the above rule should be strictly carried out. The beginner should also bear in mind that he should endeavour to tone even. By toning even I mean, to tone all prints of the same person alike.

Some of my readers might say it means to tone the whole batch of prints to the same tone or tint. Now I suppose that this could be followed out, but would it be called “artistic toning” to tone blondes, blondines, and brunettes all the same tint, and make the light hair in one face black when it is red through, and make another black, and another red black, &c.? You may say that red hair takes black, which it surely does, but if it lies in the power of the toner to tone the hair red, at least a little so, should he not do so? Another person may have black hair: should not the toner get a good dark-brown tone on the print, so as to make the hair look black (which it will do when the print is dry), and thus make the print more in keeping with the original? Should not a blonde have her hair look light in tone, and neither red nor brown, but about somewhere half-way between? The negatives of the last-mentioned class of subjects are generally so made that when you tone the face as per rule given above, the hair will be all right. So it is generally in by far the
majority of cases, the yellow and red hair being exceptions. Of course, you cannot obtain, and I doubt if you wish to obtain, the yellow tones for the hair; but if such hair is taken nicely in the negative it will very often come round to the right tint in the print, without masking the rest of the print at all yellow, but of a light-brown tint. While writing this I have in my mind such a print, wherein the hair is of a faint yellow tint, and the draperies, background, &c., are of a rich brown tone. I have obtained much of the same tones as this one by the use of the “citric acid toning bath.” Excellent tones for the red hair, with clear light-highs and half-tints in the face, are easily obtained with a bath containing chloride of sodium in its composition. The young beginner might obtain a few ideas by the close perusal of the preceding chapter about toning-baths.

You might say that it is a difficult thing for a toner to tone his prints in the style spoken of above, and also that he cannot tell when the hair should be a decided red, black, or medium, on account of his never having seen the original. For this reason it is advised by some photographers that the operator should do the toning, as he knows more about the “style of beauty” than the printer, who never sees the original. As far as lies in the printer’s power to tone the print as near as he can to proper colour, and his guides should be the original. A lady was the possessor of “lovely (?) aurora hair,” once said to a photographer. “Why, you have made my hair jet black, when it was aurora!” “Yes, said a friend, “they have made your lovely black hair, sure enough!” Red hair was the fashion at that time. I know of many first-class photographers that dislike the red tones for the reason, as I have heard them say, that “they are not artistic.”

There is a great diversity of opinion among first-class photographers about the proper kind of tones to be obtained, as many of us are aware. I myself have always admired the German portrait stereographs, the tones of many of which, I think, are perfect. It is not only in the portrait work that this toning is to be so observed, but it should be more so in landscapes, marine views, &c. Always tone them more than you would portraits, as red tones on views are abominable, and then by toning them a rich brown the finished print will look as the views do in nature, and trees, rocky cliffs, fences, wood-piles, water, logs in water, reflections in the water, steamers, &c., will all be delineated in the print with wonderful fidelity.

Weak prints should be toned in a very weak toning bath. A bath very thin, the bath very weak, and face down in the solution. Intense or hard prints should be toned quite quickly in a strong bath, and face down in the solution. Prints face up in the toning bath tone slower than when face down. Weak prints, in all solutions, should be subjected to mild treatment. A black tone is obtained by toning full strong in almost any bath if it contains a trace of chloride of lime. A chocolate tone is obtained by toning a little longer than what you would for a red tone, in almost any bath except the chloride of lime bath, and sometimes it can be obtained in this bath in a greater or less degree, according to the quality of the negatives. A decided brown tone is obtained by toning a little longer than what you would do to obtain a chocolate tone. To obtain a purple tone you should tone between chocolate and brown until the print commences to show the least possible signs of this tone, then take it from the bath and fix and wash, and when it is finally all finished it will be purplish in tint. The “sal soda bath” is excellent for these kind of tones, and they are quite easy to obtain, especially if the prints are strong, bold, and possess good toning qualities. A “nitrate of uranium bath” is also excellent. A blue tone is obtained by almost any kind of a blue; and a pretty blue is a little harder to obtain, unless the negatives from which the prints were printed are excellent ones, containing good toning qualities. The “bicarbonate of soda” is an excellent bath to obtain rich blue tones.

All of the above tones are obtained more by removing a print at certain stages of the toning from the solution than by any particular bath, although some baths may be better than others for producing particular tones. It is in a great measure, however, simply a matter of taste and experience.

PHYSICAL PROPERTIES OF COLLODION FILMS.

By W. N. Orpin.*

In a film of colloidion is poured upon the surface of a very clean glass plate, it may be separated from the glass, after drying, in the form of a very thin transparent sheet which can be placed in a frame. This membrane, with its polished surface, reflects light in the same way as glass; it polarises light both by reflection and transmission. The maximum angle of polarisation is 33°55'4", reckoned from the surface, Whatcher's normal. From this we deduce that, according to the law of Brewster, colloidion has an index of refraction, n = 1.5108-1, which is rather higher than that of crown glass.

It is possible, with the aid of this index, and by observing the displacement of the fringes of interference produced by a membrane of this kind, to calculate the thickness thereof. The membrane, upon them, was found to have a thickness less than 0·01 of a millimetre, the numbers varying from 0·0081 to 0·0088.

Through this extremely thin screen the membrane of colloidion allows a large proportion of radiating heat to pass. Taking as the sources of heat, sometimes the flame of a moderator lamp, sometimes that of a candle placed in the focus of a metallic reflector, and maintained at a constant temperature, it was found that the membrane allowed 91% of the luminous heat to pass. When a blackened can of boiling water was taken as the source, + the proportion of heat which was transmitted was not more than 70%. If the can were maintained at a temperature of 50° C, only 0·60 of the heat passed, and this amount did not sensibly decrease when the temperature of the source was 20° lower.

When two films of colloidion were placed in the track of the heat emanating from a can heated to 100° C, the amount of heat transmitted was 0·583; the first transmitted 0·70 of the heat, and the second film allowed 0·80 of the heat which traversed the first screen to pass through it.

It is possible to form polarisers by means of colloidion films. They may serve both for light and for heat. At the same time they may be dried, or exhausted, as anyone pleases, for the films are apt to break when submitted to an excess of tension. The polarisers are formed by cementing colloidion films upon tiny plates of zinc cut in the form of frames, superposing and inclining the sheets of colloidion at an angle of 30°-35° upon the direction of the rays. They have a transparency much superior to mica, which is usually employed in researches upon heat. If the polarisers are more fragile than those made from mica, they are, on the other hand, more easily repaired.

If two instruments, each composed of six films, are placed to intercept the heat rays, it will be seen that those crossed, in which the planes of incidence are perpendicular, only allow 0·66 part of the heat transmitted by the parallel instruments to go through. By placing nine films before a Nicol's prism, and noting the deviations of the galvanometer when the principal section of the prism is parallel or perpendicular to the plane of polarisation of the films, it is found that the polarised heat consists 0·6 to 0·7 of the pencil transmitted.

The facility with which anybody may construct polarising instruments, and the superiority of these in some respects over those of mica, will, the author thinks, justify their employment in heat investigation.

* Gramma Zambus.
POISONING BY BICHROMATES.

We have more than once called attention to the poisonous action of salts of chromic acid, whether taken internally or absorbed through the skin. A recent case described in the British Medical Journal by Mr. Louis Lewis, M.R.C.S., again calls attention to the importance of caution in relation to the use of this particular substance now familiarly used in photography. In the case in question an operator mistook the yellow-looking solution for pale ale, and took a good draught before he discovered his mistake. Fortunately, medical aid was speedily obtained, and by the prompt administration of sulphate of zinc, till vomiting and purgation had been induced, and subsequent exhibition of olive oil, the patient recovered, remaining, however, very weak for some time, the stomach tolerating the blandest food only.

It may be useful and interesting here to repeat some details we gave in our volume on printing in pigments, on the poisonous action of bichromates generally. Most of our readers know that, taken internally, they are active poisons; but, fortunately, up to the present time, few cases appear to have occurred, or at any rate, to have been placed on record. Dr. Closs, who made a careful investigation into the condition of health of the people engaged in a bichromate manufactory, states that, taken internally, it is not poisonous in such minute doses as cyanide of potassium, about fifteen grains being necessary to cause death in a healthy adult person; but it is in coming in contact with the mucous membrane, or with a slight abrasion of the skin, that its most injurious action is found—obstinate and dangerous ulcerations, issuing occasionally in complete destruction of the part, ensuing. It is to be observed that when used with care, no danger whatever need be apprehended, as it is quite innocuous on the skin when there is no abrasion; no absorption of the poison taking place, except by the mucous membrane, or through a wound of some kind. The important point for photographers to observe is, to avoid contact with the bichromate, where there is any scratch or lesion of the skin, and to avoid contact with the eyes or nostrils with fingers which have recently touched the chromic salt. Dr. Closs says:

This salt (bichromate of potash), in small doses—say a few grains—acts as a purgative; if in larger doses—say fifteen grains—it is a poison. A workman in a factory put some bichromate into a barrel of cider, by way of joke. The cider was rendered dark in colour, but still the other workmen drank of it, and were all affected with severe colic and diarrhoea. Disease of the nostril has been produced by workmen who, having stained their fingers with the salt, have put them into the nose.

In transforming neutral chromate of potash into bichromate, by means of acid, the vapour arising carries with it an infinity of pulverulent molecules of the product, which spread through the workshop. This cloud of particles is easily visible in a ray of sunlight. The molecules inspire a bitter and very disagreeable taste to the palate; but as profuse salivation is the result, the chromate is thrown off in the saliva, and has not time to inflict any permanent injury. If, however, respiration be made through the mouth, the molecules are absorbed, for part which lies on the membrane, creating a violent pricking, suffusion of tears, and irresistible sneezing. In time, the membrane begins to be thrown off, and portions of it are carried into the hindermost used in blowing the nose. This process, once started, goes on so rapidly, that after a period of six or eight days the septum becomes thin, permeated with openings, and is ultimately detached altogether. Snuff-takers escape this evil.

On the skin, in its normal state, and intact, the bichromate exercises no noxious influence; the hand may, in fact, be plunged into a hot concentrated solution of the salt without fear; but the hand may also be covered with the salt for an entire day without any observed effect; but if the skin is torn or abraded, however triflingly—by the prick of a pin, for example—a sharp pain is felt on contact of the salt, and if it be left in contact with the wound, the caustic character of the salt is brought out intensely, the cutaneous tissue is decomposed, and violent inflammation is established. These symptoms are accompanied with intense pain, especially in winter, when the cold is severe. The action of the salt does cease until the cauterisation has penetrated to the bone.

When the skin is abraded, and the bichromate has produced ulceration, the best treatment is to wash the part thoroughly with a feebly alkaline water; then, if inflammatory action follows, to employ calamine, and afterwards freely apply subacetate of lead in solution.

Dr. Taylor recommends, for cases where the poison has been taken internally, emetics and carbonate of magnesium or chalk, mixed with water into the consistency of cream.

A NON-INVERTED IMAGE WHILST FOCUSING.

The old proverb says that use is second nature; but there are some things to which it is possible to become perfectly accustomed without ever feeling them natural or pleasant. One of these is the inverted image of the sitter seen on the ground glass whilst focusing. The portraitist becomes familiar with it, and regards it as inevitable; to the discomfort he may become reconciled, but he is scarcely likely to make the best use of it, and an improvement on it. What the ground down limits his opportunity of estimating the pictorial effect of a multitude of details, which may be of great importance in the final result. Mr. Joseph Byrne, an ingenious photographer at Margate, has not only felt the trouble, discomfort, and other disadvantages involved, but has provided a remedy. The "Re-Optum," as he designates a nother of his inventions, is an invention, which, with certain framework to attach it to the back of the camera, and adjust it to any required position in relation to the ground glass, the image thrown upon which is in a non-inverted position on the Rectum. The effect is surprisingly pleasant and charming: on the perfectly reflecting surface is seen the upright image, apparently more realistic than it is on the ground glass; and as it is viewed flat before the eye before the operation of examining the image with a minuteness impossible before, and with a degree of comfort scarcely to be imagined. The sharpness of every object in the picture becomes easy to examine, and the composition and arrangement are all clearly placed before the eyes, as in an ordinary picture, materially conducing to the production of higher art of the highest order as well as to the removal of cases in focussing hitherto unknown. Mr. C. E. Elliott is agent for Mr. Byrne's clever invention.

THE "HARBOGATE REST."

The head-rest has been, from the earliest days of photographic portraiture, regarded by the public as an instrument of torture—not simply a terror to moving sitter, and a
praise to those who sit well, but an engine of oppression which the malignant photographer applied with Proutesque uniformity to all his victims, protest and entreaty being alike impotent in securing immunity from its iron grip.

"Please do not screw me up!" "I can sit still without that iron thing!" It was that vice which held my head case against plate!" and a hundred similar protest and remarks are familiar to the portraitist, who, however, generally been quite satisfied that the use of the rest was imperative to prevent moving. But it is unfortunately true that the head-rest has been, for many years, more or less an instrument of torture; and, what is worse, it has often been destructive of ease and grace in position, and a forlorn expression of the model as well as a useless feature for the sitter. The old stiff unyielding rod of iron too often rendered it necessary to place the sitter to suit the rest, rather than to bring the means of rest and support to the natural position of the sitter. The true theory of the rest is suggested by its name. An easy, natural, graceful position having been secured, a support or "rest" is required just at that part of the head or body which will support that straight and steadyness of position of the sitter, the utmost pliability in the rest is necessary; and this must be secured without loss of firmness and rigidity, and without unnecessary complication. All the changes of position should be easily made, but absolutely firm support must at the same time be secured.

Considerable improvement in such rests has of late years taken place in the "Hiramic Rest," in its present perfected form, which has been submitted to our attention by Mr. Harvey, Reynolds, and Co. It seems to approach nearest to perfection, having regard to all the requirements of the sitter and the photographer, which we have seen. It is firm and rigid without being cumbersome, and possesses the utmost pliability and adaptability to every position of the model, standing, sitting, or sitting, being at all complex. Every change of position is easily made, and as easily and firmly secured, head and body each receiving comfortable support, not constraint, in almost any position of standing or sitting. A curved slot in the main pillar permits a lateral movement of the rest without disturbing the base, and also permits the rest to be thrown out of the upright, to accommodate leaning or stooping figures in groups and figures for group photographs. In short, the rest, being once placed in a moderately suitable position beside the sitter, will not require to be moved about to accommodate slight changes in position; but, after the model is satisfactorily posed, the several portions of the rest can be quietly brought into contact, and firmly fixed, without the slightest disturbance to the sitter, to whom it will be really a stay and comfort, rather than the irritating source of constraint so often, and not unjustly, objected.

---

Critical Notices.

In the handsome got up quarto volume before us, Mr. Woodbury's chief aim appears to have been to bring together in one volume a score and a half of pretty photographs of beautiful or interesting places, and so form a useful gift book. There is no connection or sequence in either text or illustrations. A "Street in Cairo" is followed by a "River Scene in Java," that by an Interior of a Mosque in Cordova, and so on; the short detached descriptive chapters by different pens being also without connection or sequence. But this somewhat desultory character is really an element of value in a book intended for the drawing room table, as it makes no demand on continuous reading, whilst it will aid in rendering agreeable many a moanous quart d'heure. The photographs are for the most part good ones, well printed by the photo-relief process; and the brief chapters attached give generally sufficient details to increase the interest of the pictures.

---

This successful, although comparatively new, competitor for the smiles of the public claims notice in a photographic journal on the double ground that photography plays an important part in the numerous very fine illustrations, and the comic aspects of photography are frequently made subjects of good-humored fun in the new journal. We strongly recommend it to our readers, of the cheapest and best yet issued of the mirth-compelling weeklies. Here is an extract which will amuse our readers:

"The Whistling Photo."

"But the month's whistling. You can almost hear it!"

So one day says the Cliff to Ben the farm photographer.

And the thing's so droll they can't help laughing over it, and wanting to know how it came about. So I may as well set down the story, once for all.

It was a hot July day, and our village was baking in the sun.

The heat made us all lazy and dozy, and the look out for anything that might happen, when all of a sudden the whole place was woke up."

There was a hearse on the Green!"

We couldn't believe our eyes. Nobody was dead. There hadn't been a funeral thereabouts for six months. What did it mean? Nobody had an idea. But there was the hearse. No mistake about it. And what made it the more surprising was that the horse in the shafts was white, with spots like wafers all over it—not what under-taken a horse would usually like.

You may be sure we flocked out to see what it all meant, and a white-faced man in a black cloak, who was sitting the nose bag on, looked up, bright and smiling, as we gathered about him.

"So it's you, I thought," he said, "that drew you, ha!

"What 'dey mean by 'drawed us'?" demanded the landlord of our inn—the Blue Boy and Spud.

"Ha, ha!" cried the pale man, throwing off the black cloak. "I'm an artist, I am, and I've got to draw my customers before I photograph 'em. Now there's nothing fetches 'em out like this travelling convenience"—pointing to the hearse. "Whenever they see it in any village, they're sure something's up; and as it seems to be a weakness of human nature to take an interest in seeing friends and relatives buried off and out of the way, I'm never long in getting round me an intelligent and enlightened assembly like that which I have now the honour of submitting specimen of my art, "Aft-a-crown—shilling—sixpence."

He had taken from under his cloak, as he was speaking, small caskets in cases, and now handed them round. Then he proceeded to open the door of the hearse, and to drag therefrom a camera, the stand for it, and a number of articles useful in his art.

"Handy, you see," he remarked, still in reference to the hearse, "so carry things in, as well as to get the best thing in the world for a dark-room—the original one, in fact."

Talking on, he had by this time ripped up his camera, brought out the little box with the prepared plates in it, and was ready for a customer. We were taken with the humour of the man, but all a little shy. But out comes Matt Jones from the Blue Boy, striding along with that viscous bull-terrier of his at his heels.

"I'm on, man," says the man. "I'm on!"

"Certainly, sir, certainly!" says the pale man, looking about with an air of business; "take the camp-stool, sir, and sit here—just here, and I'll do. Stool, please.

He laid his hands on Jones's big broad shoulders to get him into position, and as he did so an ominous growl from the bull-terrier was audible.

"Lie down, Growler!" cried Jones, and the growl subsided.

The artist retreated to the camera, made his preparations, and was ready to begin. His head disappeared under the black cloth.

"'Steady, sir," said he, reappearing, and throwing himself into an attitude, "please to fix this thing for a minute, and I'll do a little more straighter—that's it. Now, perfectly still, please, till I tell you."

The expression which at that moment came into Jones's face was curious to behold. He was afraid to move his head, but even without doing so he could perceive a suggestive movement on the part of Growler. He saw that treacherous beast, who seemed for the first time to have taken a kindly interest in the artist, advancing toward the thrust-back calf of that individual, who stood watch in hand. It was a critical moment. Jones didn't like
to spoil the chance of a good likeness by calling out "Down, Growler!" and for the same reason he didn't care to let the beast fix on to the tempting calf. A compromise suggested itself. He gave a low whistle, without moving his lips, as he believed, and the dog hesitated; he ventured on a louder, and the brute glared at him; a louder yet, and he slunk back.

"But the artist had seen the lips twist.

"Confound it, sir!" he cried out, raising his arms in a passion, your whistling'll spoil all, you.

A yell ended the sentence. Growler had spoilt it. Believing that an artist was meditating, he had darted forward and fixed his teeth in the plumpest part of the tempting calf. Down went the artist, down came the camera, forward darted Jones, and through and over the dog, and the smashed apparatus were all mixed up in the wild struggle on the ground. It was a minute or more before Growler could be beaten off, and when his victim was released from his fangs he was not in a state to take more portraits that day.

Next morning the beast was gone, and, strangely enough, has never been seen there since.

But Jones had secured his picture—his mouth distorted with the whistle in it; and there it hangs in the bar of the Blue Boy and Spud, known to everybody as the Whistling Photo.

**FRENCH CORRESPONDENCE.**

**DUOUC DU HAURON'S HELIOCROMIC PROCESS—VANDER WEYDE'S NEW METHOD OF LIGHTING—BOYMIA AND VIDAUX'S PHOTOGRAPHIC MANUALS.**

While M. Leon Vidal is preparing for the practical working of his heliocromatic process in the establishment of the **Moniteur Universel**, M. Ducou du Hauron, whose name is also familiar to your readers as a worker in the same line, has continued his investigations into the prove his process by a method different from the one he lent to the composition of the late collodion, and rendered it sensitive to the red and green rays.

As to the pigmented papers, yellow, red, and blue, which he employs for the production of his prints, M. Ducou du Hauron prepares them in the manner following:

In making the red paper, he dissolves ten grammes of carnate in a litre of ammonia, which is poured into a green bath. After several hours, when the ammonia has reacted so as to leave scarcely any odour behind, he adds rain water in sufficient quantity to fill up the original measure again. Then he takes sixty-five cubic centimetres of the solution, adds thirty-five cubic centimetres of rain water, allows about fifteen grammes of soluble gelatine to soak in the same for an hour, adds one gramm of sugar, and makes a solution of the above in a water bath heated to 50° or 60° Cent. He then filters the mixture, still warm, by the water bath; and, finally, he pours into a graduated glass measure the quantity of mixture necessary to cover the sheet of paper, the latter being put upon a glass plate previously to the mixture being poured over it. When the gelatine has set, the paper is taken from the glass plate, and put to dry in a stove, the temperature of which is constantly kept between 18° and 22° Cent. To prevent the paper, from contracting, it is placed, whilst drying, between a pad of blotting-paper and a wooden frame, the weight of which is sufficient to maintain it in a flat condition.

To prepare the yellow pigmented paper, M. Ducou du Hauron pours in a mortar twenty-five grammes of clear chrome yellow (water colour), adding by degrees rain water, until they are reduced into one hundred and seven grammes of this liquid (which is shaken up before it is used) put fifteen grammes of gelatine and one gramm of sugar; and, after this has remained for an hour, you proceed exactly as above.

For the Prussian blue pigment paper, M. Ducou simply employs the permanent blue ink of commerce (15 cuts. cent. m. 80 c.c. of rain water), and he proceeds to treat this exactly the same manner as the red and yellow pigmented paper.

The three papers thus prepared are sensitized in a bath composed of 100 grammes of bichromate of potash reduced to powder, dissolved in a litre of water. A little ammonia is added by degrees, the mixture being stirred the while until the dark-yellow colour of the solution becomes really clear. To be quite sure that the whole of the bichromate of potash is combined with the ammonia, an excess of the latter is added, the odour of which indicates when there is no further combination taking place. According as the weather is warmer or colder, twenty to fifty grammes of sugar are added to the bath per litre of solution.

The period of immersion of the pigmented paper in the sensitizing bath varies also with the temperature of the locality in which the operation takes place, the gelatine absorbing far more liquid in a given time in hot than in cold weather. The immersion should take from two to five minutes.

When the pigmented tissue has been printed under one of the negatives, it is covered with a slight film of normal collodion (five grammes of pyroxil dissolved in 100 cts. centimeters of a mixture of ether and alcohol), and after desiccation the sheet is plunged into a cold water bath, at the bottom of which is placed a glass plate covered with a thin film of wax. The glass and the paper are withdrawn together, the gelatined side of the latter being in contact with the waxed surface, and their perfect adherence is further assured by employing an Indian-rubber squeegee. After a few moments the hot water has been in contact with the glass and the paper are plunged into water moderately warm contained in a zinc bath placed upon an oven. The paper soon becomes detached, and the developed image remains upon the glass.

To transport successively to the same sheet of paper the three monochromes, red, blue, and yellow, thus obtained are printed on different glasses following the same process.

An alcohol bath is first prepared by mixing two parts by volume of alcohol at 31° with one part of water. This solution is poured into a horizontal bath, and a glass plate bearing the yellow monochrome is plunged into it, together with a sheet of gelatined paper; after a few minutes the glass is taken out, together with the sheet of paper, maintained in contact by a thumb and index finger of the hand as close to the gelatine facing. A rubber squeegee makes adherence more complete, and after it is thoroughly dry the image adhering to the paper leaves the glass plate. If the separation is not effected at once, however, the glass plate is slightly warmed, when the yellow image detaches itself with ease by lifting one of the corners.

To dissolve away the collodion and the traces of wax adhering to the monochromes, these are immersed for an instant in an alcohol and ether bath. When the ether and alcohol absorbed by the paper have evaporated, M. Ducou proceeds to the application of the yellow monochrome to the blue one. To do this, he immerses in the alcohol bath of 60°, which has already been employed in the process, the glass carrying the blue monochrome, and the paper bearing the yellow monochrome; and after a few moments they are mixed together. In the presence of the light, the separation being then proceeded with as above. In this case, however, it is necessary to pay attention that the outlines of the objects coincide; this is done by looking at the prints as transparencies, and drawing one gradually over the other, an operation that is facilitated by the circumstance that one print is upon paper, and the other upon glass. The operation being thus accomplished, the aden is effected in the same way as before, and afterwards the third monochrome image, the red one, is superposed on the other two in the same way. The compound print is finally mounted on Bristol board; but before this last operation it is well to immerse the image for a few minutes in an alum bath, which, among other advantages, has that of rendering the curmatine perfectly permanent. The paper which serves for the definite support should be well faced
with gelatine, and for this purpose a ten per cent. solution is used.

The mode of printing which has just been described may, as M. Ducos du Hauron observes, be applied to the production of heliochromes upon glass—that is to say, vitrines, stained windows, and the like. To secure perfect adhesion of this emulsion is only necessary, after having produced a heliochrome upon paper, to immerse it in an alcohol bath as above, and to ensure adherence in the way already described, the glass having previously received a very thin film of gelatine treated in alum.

It is obvious that the whole series of operations here described is very ingenuous, and evidently M. Ducos du Hauron has made much progress since his first publication on the subject. The working of this invention, however, is still difficult, complicated, and requires important simplifications before it can be worked practically. We know, too, that the intelligence and activity of the inventor will speedily overcome the difficulties that now attend the operations, and which at present render any industrial use of the process impossible.

I received this week a visit from Mr. Vander Weyde, who desires to make known to French photographers his new method of lighting studios. He is already in communication with one of our principal portraitists for the establishment of a model studio where his patent may be worked and exploited. The invention, of which he has already communicated to me the principal points, is of most ingenuous and very successful. Mr. Ernest Boivin, of Marseilles, whose communications I have on several occasions reproduced in these columns, is going to produce a work very shortly which will certainly be well received by photographers, for it will contain a résumé of the process which has lately taken place in the production of negatives by the dry-plate process, and in printing in carbon. These are both of them subjects which are at present pregnant with importance, and the present operators with a summary of the improvements accomplished recently in these two branches of the art, M. Boivin will render a sensible service.

It appears that M. Leon Vidal is also engaged in preparing a new and enlarged edition of his excellent manual of carbon printing. 

PRACTICAL PORTRAIT PHOTOGRAPHY.

BY WILLIAM HEIGHWAY.

CHAPTER II.

The manipulations of the dark room are so important, and their success is dependent on some apparently trivial circumstances, that it will be well for us to use all the time and attention the subject of this department, how to secure a room as nearly perfect as possible. In many cases, of course, the room is already set out and fitted up according to the ideas of some former tenant; or, if building for yourself, it may be found that your ideas must be modified considerably to suit the accommodation at your disposal. It must be an idea for a dark-room as a whole, and leave it to the intelligence of the reader to follow it with such modifications as circumstances demand, or its ingenuity devises.

It should certainly be in the immediate vicinity of the skylight, for quickness and success of working; and this consideration should outweigh many even grave objections to its immediately adjoining the glass house. So many dark rooms are to be found that are thoroughly unsuitable to the purpose for which they are designed (?), that if the reader has ever attempted to work in them he will recognize the great necessity for placing it certainly on the same floor as the glass house, and easy of access.

The room should be wholly lined with wood closely fitted, and without crack or aperture to admit scintillating light. The ceiling should be painted in, to allow of dust and dirt being wiped off as occasion may require. Do not fall into the fond error that shelves are "so handy." A shelf for the plate-holders, one for the glass plates and collodion pouring-bottles, and one handy to the sink for the developer and strengthening solutions, are as many as you require; others only harbour dust, and tempt you to make use of the dark room as a common receptacle for rubbish. Everything like chemicals, bottles, and negative papers, &c., &c., must be banished—everything but that immediately appertaining to your work. Dust is one of your most insidious enemies, therefore you paint your walls and ceiling, because paint does not retain it so readily as paper and rough wood, and is easily cleaned, consequently you are not constantly troubled with dust falling from walls and ceiling. For the same reason you have only those shelves you absolutely require, they being easily kept clean and you are not tempted to bring round you a choice collection of rubbish.

The size of the room is a very important consideration. Let it be as small as possible, consistent with comfort; one eight feet by ten or eleven ought to be ample for almost any amount of work. This room should be kept most scrupulously clean, and for this purpose a mop should be used every morning to clean the floor. Sweeping is not tolerateable, as it raises dust that troubles you long after the operation. A sash about two feet square, glazed with orange yellow glass, should be let in immediately over the tank, the light of which allows you to watch the development of your plate. See that this window is neither too high, rendering it useless, nor too low for comfort, so as to be out of your reach and. Cooling and health are things which should be studied in photographers' quarters, as there is quite enough to try the patience and constitution. The sash is to be provided with glass or shutters, light frames covered with yellow paper, that may be easily let down to cover the window when it is necessary to shut out a portion of the light. By all means have a window which is openable when not in use, for the purpose of ventilating the room.

Where it is not possible to have a window at which to develop, the only thing left to you is to have a shaded gas-burner fixed a little lower than the level of the plate in your hand. The shelf for the plate-holders should be covered with several thicknesses of blotting-paper to catch any drippings of silver (which should be few) from the plates. These sheets, when they are taken up as being dirty or full of silver, to be sent to the assayer to extract the silver, and fresh ones put in their place.

The tank should be of sufficient capacity for a day's work, that all the washings may be kept till the end of the day to be precipitated, and to allow of the clear water to be drawn off the first thing in the morning. The tank may be about three feet high, and rest on the floor, eighteen inches in width, so that the window, the illumination of which aids you in determining the development, may not be too far off, and as long as you can spare space for. The water with which you wash off the developer at the point of proper delineation is admitted from a reservoir by a pipe holding the tap placed conveniently under control, which should admit of a clear and plentiful stream running down the back of the plate. This should also be fixed another tap with a little tray, independent of the main tank, at which you can wash the negative when fixed, the soda or cyanide washings being carried away without passing into the tank. But of this, further when the subject of manipulation engages our attention. The tank should be fixed with a false bottom, making a tray eighteen inches deep, and the reception of used glasses. This false bottom is perforated with holes, through which the water is running the tray dry; below is fitted a waste pipe let into the tank about a foot from the bottom, the end inside the tank being carried down to within two inches of the bottom, by which means, in letting off the waste, the silver deposit at the bottom of the tank is not disturbed. Of course it will be seen that for this pipe to empty the tank to the level of the end inside the tank it must be lowered on the outside of the same level fitted with a tap, that the wash...
ings may be retained till they can be precipitated with a saturated solution of copperas, a common salt of iron.

The accompanying little sketch will explain the arrangement of the tank, which must of course be perfectly watertight. T T are the taps at which the negative is washed.

that over tray C for the negative after development, the washings running into the tank; and the tap T over tray marked B, for washing the negative after fixation, the washings of which run away down the pipe indicated (A) on the left of the diagram. The pipe on the right (W P) is the waste pipe of the tank, the tap (D) at the bottom retaining the contents of the tank till it has been precipitated with the saturated solution of copperas.

The dark room should be kept as nearly as possible at an average, comfortable temperature all the year round, as much for the sake of the work as of the worker. A little stove should be fitted in the winter to warm the room to about 60°, and in summer the operator should seek by means of ventilation to keep the thermometer from ranging into the eighties and nineties.

Much trouble is saved, and good order assured, by having an apartment appropriated to the purposes of a chemical room, in which to boil baths, clean and albumenise glass (if you decide on accepting my suggestions in favour of this latter operation), and for keeping chemicals, bottles, graduates, funnies, &c., &c. A small cupboard may be fitted for the reception of the various chemicals; separate utensils, bottles, and funnels should be used for the various solutions, and should be kept to their proper use. Let all your bottles be kept clean, and be neatly labelled.

THE WOODBURY PROCESS.

BY W. R. BAYNE.

The process I am about to describe is one which it is my firm conviction is destined to play a most important part in the future of photography. As a discovery it will rank in importance next to that of the collodion process, and will link the name of Woodbury with those of our greatest discoverers. In printing operations it will ultimately prove as great a boon as collodion did in the negative processes of old.

The principles involved in the process are few and simple, and they ought to prove a lesson to us as to what may be produced with genius from apparently insignificant means.

The essence of the Woodburytype is a fact well known to us all, and has proved to be the starting-point of more printing processes than I could enumerate in the time at my disposal. I refer to the circumstances that gelatine and other analogous substances, when a bichromate is added thereto, become insoluble under the influence of light.

A moment's reflection on this will show that a layer of such a bichromated gelatine will, after the unequal action of light and subsequent solution of the soluble portions, present a film of varying thickness. Suppose, for instance, I had a film of this nature, and upon it I placed, say, a penny (an article, by the way, more familiar than a five-pound note), and then exposed the whole to the action of light; clearly, all the portions but that covered by the coin would have become insoluble; and were I to dissolve away this covered portion I should have as a result a hollow disc corresponding in size to a penny, and, as a master of course, raised portions all round. Now this action is found to bear an exact but inverse relation to the density of the negative; in other words, the action is greatest in the parts under the clear portions of the negative, less under the half-tones, and so on, until the parts protected by opacity are totally unaffected. Thus not only would a negative be represented on such a film or tissue in raised and sunken portions, but the deviations and hollows would also bear a perfect relation in relief to the shadows and lights of the negative.

As it may aptly be termed the "back bone" of the process, I will proceed to enter more minutely therein under the heading of the "relief." A bichromate is intimately mixed with a quantity of gelatine and water, and this is poured upon a plate as a support, and dried. This, as you will perceive, is similar to sensitised carbon tissue minus the colouring matter. With talc as a substitute for the paper the use of the transparent support will soon be obvious; other media besides talc may be, and are, used. The drying of these films is a troublesome operation; but, let this process once come fairly into play, and a little pressure on the rollers will bring into the market a tissue with paper as a support to be sensitised, dried, and developed like a carbon print.

Now suppose ourselves in possession of a film of this kind on talc, of which I must know the means for printing the same. You are all aware of the necessity for developing from the back in the case of carbon printing in order to preserve half-tone, and as we are dealing with similar materials it would be a waste of time to point out the necessity of the same rule being observed here. The use of the talc now appears. Being transparent it enables you to print from the back, and thus save transferring; so we will suppose the talc and gelatine placed in contact with the negative, from which it is desired to obtain the relief.

Now comes a most important point—one which, unless attention be paid to it, will bring about certain failure. I can best illustrate it in a manner familiar to us all. When it is desired to print a vignette, to produce this effect a piece of onedothboard with a suitable print is used. We all know the result of placing it in the direct rays of the sun. You obtain thereby a tolerably sharp counterpart on your sensitised paper of the opening in the cardboard, with your picture, perhaps, struggling in at one side—an effect which cannot be pronounced either neat or gaudy; yet, when the same arrangement is printed in diffused light—or, as it is termed, "in the shade"—quite another effect is the result. How about it? It is quite difficult to explain, and, indeed, would it be necessary to attempt to explain an effect the cause of which is so obvious.

Now let us return to our negative with the sensitised film in contact, and examine it. Obviously the gelatine has an appreciable thickness, and parts of the relief are, therefore, formed at some distance from the negative. Your attention need not be drawn to this circumstance to see that if diffused light were used for printing a relief, the result would be more or less indistinct, and hence only parallel rays must be used in order to obtain a sharp image. This condition may be complied with if you print in the sun, of course keeping out diffused light. Artificial light may be employed. Mr. Woodbury used the electric light, which, however, will be found costly to fit up, besides increasing the exposure considerably. Whenever the relief is produced the effect after development is such as you now hold in your hands.

We now proceed to the production of the mould. At first electrotyping was employed; but this was superseded by the discovery of Mr. Woodbury that hydraulic pressure might be used. The delicate gelatine relief is placed in contact with a plate of metal, and these, placed between two perfectly true steel plates, are then placed in a press and subjected to a pressure of about four horse-power. It is my opinion, that it is here where the chief difficulty hitherto operating in the non-application of this
method of printing is to be found. The hydraulic press is a piece of apparatus few, indeed, would add to their plant. If ever the photo-relief process becomes generally employed, one of two things must take place; either some firm will undertake to make the moulds, or some method better suited for general application must be employed. To this latter point we will devote a little time. Casting in wax, sulphur, and other analogous bodies, is not to be despised. A gentleman (and, I care I now remember his name) has called attention to the use of sealing-wax, and shortly after doing so gave a very valuable method whereby moulds can be easily made with a piece of apparatus which many of us have discarded— I mean a rolling-press. A piece of soft type metal was placed in a shallow steel box so as to allow of the type metal projecting slightly above the edge. Upon this was placed the relief, and a steel plate again upon the whole, and run through the ordinary rolling-press. A moment’s reflection will show that no distortion can take place if care be taken not to have too much metal projecting.

Again: Mr. Woodbury names a means, included in a recent patent, where tinfoil is pressed into the hollows of a relief, and this is again backed with a suitable material. I have not seen any production of this kind, but think they must be similar to those patented by Mr. Dallas in 1866, as he says:—"I also mould with tin, lead, or other metal foil by beating it with a brush," and then some adhesive material is pressed well upon it. He further says:—"Sunk surfaces prepared accordingly to my invention may be employed to produce prints with half-tints." After describing the method, he says:—"This method of printing is now known as photo-relief printing." Perhaps you have had enough of the "relief," and to relieve you I will treat of the last point, viz., the printing, which I can put into a very few words.

The principle involved in this operation is, that varying thicknesses of a semi-transparent material give corresponding variety in the depth of tone; so that if a mould be filled with a semi-transparent mixture, but portions which occupy the hollows pressed out, and a material be furnished to which the ink will adhere, the result would be a print in perfect half-tone. This is what is done in the process now under discussion, and some results of which you now see. My object is accomplished if I have turned attention to the most valuable process not in general use—a process destined to mark a new era in our art.

Correspondence.

WASHING PRINTS.

Dear Sir,—Will you allow me space in your News as regards the final washing of photographic prints? I will give a plan I have used for the last year, which, although a very old one, is a first-rate plan. After the prints are removed from the hypo, I place them in a pail of water with some chloride of sodium (common salt) for five minutes, and then I place them on a glass slab large enough to hold eighteen cabinets, and dab them; then take them up, swill the slab, dab the back, and then dry them. This is an excellent plan, although old. I have three glass slabs, so I and my assistants can wash fifty-four in a very short time.—I am, dear sir, yours truly, C. R. R. VERSON.

Grafton Underwood, Kettering.

PHOTOGRAPHY IN DEVONSHIRE.

Sir,—A good suggestion was made in the Year-Book as to the publication of a photographers’ guide-book to interesting scenery. I trust some one will adopt the suggestion, and supply a real want. In the meantime, would you or any of your readers give me any kind of photographic information about the north of Devonshire? I should feel greatly obliged for information as to the central place for a few weeks’ stay, within easy reach of good subjects, together with any notes or hints, the result of personal experience.

Such information would probably be interesting to others of your readers. I would gladly, in return, give Continental notes to any requiring such.—Faithfully yours, W. A. C. A.

Proceedings of Societies.

WEST RIDING OF YORKSHIRE PHOTOGRAPHIC SOCIETY.

The ordinary monthly meeting of the above Society was held at the Victoria Hotel, Bradford, on Monday, the 8th instant, the President, Mr. J. W. Goulston, in the chair.

The minutes of the previous meeting were read and confirmed.

The Chairman proposed" 'That a sale and exchange list, for members' use only, be issued with each monthly notice of meeting, and that each notice of any article for sale or exchange be subject to a charge of threepence for the first eighteen words, and three-pence for each extra nine words.'

Mr. A. W. Birk seconded the motion.

Mr. Moir most heartily supported the resolution, remarking that it would be much more satisfactory to know the persons whom they were having transactions with besides there being a possible opportunity of seeing the article offered. He had on more than one occasion exchanged through the medium of an advertising journal, and been victimized. There was no means of redress.

Other members expressed their approbation, and the motion being put to the meeting, the chairman for the time being, it was unanimously carried.

The following gentlemen were then elected members:—Messrs. Braithwaite (Leeds), Gunson (Bradford), and Appleby (Brighouse).

Mr. Howarth then exhibited to the Society, by request, a model of his stove for heating studios, which he had inspected with much interest by the members. He (Mr. Howarth) taking it to pieces and explaining the principles of its construction.

Mr. W. E. Batho laid on the table the three carbon prints referred to in his communication on the continuating action of light in carbon printing (see Photographic Journal, March 20), which were handed round, the general opinion being that there was no material difference in the three prints. After some desultory conversation therupon, he (Mr. Batho) read a paper on "The Woodbury Process" (see page 214). A number of reliefs and copies from prints by the eminent firm of M. Godard, were handed round for the members' inspection, the prints being pronounced by several to be equal to silver prints.

In reply to a question by a Member, Mr. Batho stated that the pressure required for the production of the relief was very constant, being estimated by some at about four tons to the square inch, but he believed the prints handed round were produced with a pressure of a hundred tons, which was considerably under the other estimate.

On a Member inquiring if lead would answer for making the relief, Mr. Batho said it did not, but he said that it was not so much a matter of £ s. d. as the advancement of the art, and photographers should devote more time and attention to them.

Mr. Wormald said it was a matter of £ s. d. to most photographers. The process, he said, although carried out very considerably, was out of reach of mechanical appliances, hydraulic presses, &c. If any one could be found who would undertake the making of the reliefs it would be a different matter.

In reply to several remarks, Mr. Batho said the Woodbury process was not more difficult than any other of the methods of reproduction; but of course it required some amount of practice.

The Chairman remarked that one great difficulty with many photographers was that they received information regarding these processes by instalments, and thus did not get to know them sufficiently well. If the method was published in a concise and practical form, no doubt more attention would be given to it. A hearty vote of thanks was accorded to Mr. Batho for his very interesting paper.

Mr. Batho, in replying, made several remarks regarding the method of doing business. He was of opinion that photographers ought to discard the traditional dozen cartes, and
endavor to get larger orders, and thus mechanical printing processes would be found economical.

Mr. Berson said that there would be some difficulty in persuading the public to change its method of doing business; it had been tried by most of the photographers of reputation. He believed Mr. Sarony had tried the experiment. He had commenced doing carte portraits at thirty for £1, but he had returned to the dozen.

Mr. Wake had also tried departing from the generally-accepted method by charging for the negatives, irrespective of what number of pictures might be taken. For the first negative he charged 5s. 6d., for the second 2s. 6d., and for further negatives 1s. 6d. each; but he had not found it pay. The matter lay more with the public than with the photographer, and so long as the public chose to abide by the present method of doing business, the photographer must acquiesce.

Mr. Berson asked if any member had tried the addition of methyl alcohol to the developer, instead of the ordinary methylated spirits of wine. He (Mr. Berson) had been using it according to a formula given in the Photographic News for February 12, and had found considerable advantage in its use during the late dull weather. He was of opinion that there was a gain of almost one-half in shortness of exposure.

Mr. Afflloyd said he had also tried it, and had found a similar advantage, though he scarcely thought to the same extent as Mr. Berson had experienced.

After a little further conversation the meeting was adjourned.

Talk in the Studio.

The Royal Academy.—It is understood to be extremely probable that the Royal Academicians will, at an early meeting of the Council, take steps in furtherance of the long-since proposed reform in the constitution of the body, by adding at least ten Associates to the number established about three generations ago. Undoubtedly this will be a reform in the right direction, and it will certainly be very popular with artists, a considerable number of whom will expect to be elected forthwith. Of course it is understood that the proposed ten new A. R. A.'s will belong to a distinct class, and will not share the duplicate system of life, and pension fund of the Academy. We suppose this fund, although a considerable one, would not support so great a new demand as the reverse of this supposition would imply.—Athenaeum.

To Persons about to Marry.—The new humorous and satirical journal issued at Tunbridge Wells, the Moppee, in a capital article on brides and bridecakes, has a practical suggestion which we believe will be of use to all who wish to marry. It proceeds thus:

"Here is a note to all those who are about to marry.

"Pray don't let the word out, but we have found a sure plan which never fails. When the bride is in her best, ask her to stand in a lighted room, and say, 'If you don't like the dress, the pleats and the accessories, we will do as you please.'

"We have found that this plan always works, and never fails, and we hope this will be of use to all who are about to marry."

No Correspondents.

VENATOR.—The flux mentioned will answer your purpose well. The article is altogether a good and practical one, and you may keep it for future use.

Mr. Angel.—We are receiving the details of your method of making a bellows for a camera. Of course the first the photographer desires the thanks of the society, rather than those who retain for their own private improvements which they work out.

GALA.—The yellow spots are without a doubt due to the bromide powder used in the "gold" printing on the cards. The "inhibitor" used with the bromiding machine would not have any very good effect. A very slow effect, but no reason for concern. The bromiding process would aid in distributing the injurious particles of bromine over the surface of the prints.

A READER (ALAN C.)—It is scarcely probable that you could observe any very great effect by examining a year's negatives for this one year, and printing and printing in the pressure-frame, to produce a negative, etc., etc. It is probable that both surface and texture would be irregular, and produce greater results for the first time. It is sufficient printing force in such images. You will do wisely to present the recognized beaten track of photography until you have mastered the technical details, and acquired manipulating skill; then you will have the advantage of improper experiment and try novel plans. It is not necessary or desirable to tone a paper negative at all, as the brown tint produced by simple fixing in the hypo bath is best for negative purposes. Paper prints may be fixed.

Cadmium.—If the surface of the Daguerreotype have been scratched by the rubbing to which you refer, there are no means of restoring its pristine beauty. Washing with a weak solution of an aqueous solution of potassium will remove the tarnished effect which sometimes follows exposure on a Daguerreotype; but, if possible, you should entrust the work to a photographer who is familiar with the treatment of damaged plates.

LEROY.—The spot on the negative to which you refer is what is commonly known as a comet, and is probably due to the colloid, in some insulated or unexposed particle has been present. Similar colodium iodized with iodide of potassium is very liable to this trouble, small particles of the salt, or impurities in the salt, remaining in suspension in the colloid, and causing insipid appearance with tails; the tail itself generally running in the direction that the colloid flowed on the plate.

PYRO (1.)—We have published many formulae for retouching various kinds of prints, and instructions for the mode of using them. We cannot with propriety occupy the columns of the Photographic News in the future with such instructions. A very good varnish of the kind may be made by dissolving thirty grains of gum dammar in an ounce of spirits of turpentine. In recent Year-Books you will find many formulae of the kind.

ONE IN THE TRADE.—Mr. York added five grains of nitrate of silver to each ounce, and found that answer. It has, we believe, a tendency to gradually increase the density of the picture. It is one of the general experience teaches, injure sensitiveness. Acetate of iron gives intensity, but does not permit of decreased exposure. It is only desirable to use it when there is difficulty of getting sufficient intensity. If you wish to use it, you must prepare it yourself. The addition of a drop or two of liquid ammonia to the ordinary iron developer containing acetate of iron will form a portion of acetate of iron in the solution, as will also the addition of acetate of soda. It may be made by adding a solution of acetate of lead to a solution of sulphate of iron, filtering out the sulphate of lead, and treating the acetate of iron with the solution of the developer. They are, in our opinion, an improvement; and if added in a very large proportion, the proportion of the acetate of iron may be reduced.

YOUNG BEGINNER.—It is difficult to answer your question as to the amount of possible study at a good school. You will, of course, be much the better of the experience which you gain, but much the worse of the experience which you lose. As much depends on the standard of excellence you set up. If your means and space impose limits, you may do good work in a house 15 by 10 feet, using a good quarter-plate lens. No. 2 or 3 of the lenses you name will answer for views and general purposes.

P. M. SUTCLIFFE.—We have on more than one occasion met with cases in which photographs printed with India-rubber solution in an album have been discoloured. The India-rubber itself undergoes decomposition, and acquires the character of a brown resin. The prints you enclose have precisely the character of those to which you refer. The yellowness, or brown tint, is not the ordinary type of photographic fade, but is the result of decomposition of the India-rubber, which had partly permeated the substance of the print. One of the best mounting materials we know for the protection of photographs is a 30% alcohol solution of gelatine which we described some time ago, and which is sold under various names, such as "Parlour Paste". "Marion's Mounting Solution," &c.

ASSUR.—The experience you relate is annoying and perplexing; but it is difficult to suggest a remedy, unless you are prepared to recover the silver from your residues yourself. We shall have something more to say on the subject in our next.

B. SLADE.—We have forwarded the address.

PERPLEXED.—It will be impossible to do really fine work regularly in such a studio as you describe. The lighting of the spacious entrance is certainly very good, but you may work much out of focus. The best plan you can adopt will be to have a very complete system of blind to cover at will the east side and half the top on the same side, and the west side and half the top on the opposite side, using the room in the afternoon. Tissue-paper or tracing-cloth answers best for keeping direct sunlight.

Several Correspondents in our next.
PHOTOGRAPHY IN AND OUT OF THE STUDIO

Photography and Wood Engraving—The New Foreign Fellows of the Royal Society—Absolute Alcohol.

Photography and Wood Engraving.—Nothing seems easier to a photographer than to produce an image upon a wood block for engraving, and yet, practically, there are few more difficult operations he can have to do with. The print is required sharply limned upon the box-wood block, so that the engraver may see every detail of the picture, this being especially necessary if the image is not the reproduction of a drawing, but an object from nature. In the latter case, there are no lines shown, but only dark and light tones, and a very good cutter indeed is necessary, who must himself be a bit of an artist in order to reproduce by lines, sufficiently thick and close together, the dark tones of a photograph under his hands. One very serious difficulty occurs at the outset, and that is the expansion of the block in water or a liquid of some kind. In order that the block should not suffer by such treatment, one of very good quality must be selected, consisting of three or four centres, well fixed together. If the block is to be coated with a thin film of albumen, or some such material, first of all, it is of course necessary that the surface should be wetted; and the same holds good if a carbon image is to be developed on or transferred upon the surface of the wood block, by some ordinary procedure. In doing this, there would be no absolute need for moistening the surface. Unfortunately, the wood engraver dislikes any trace of grease upon his block before it is cut, and if any assistance from a draughtsman's pencil is necessary, no touching can obviously be done upon a greasy surface. There is also an objection to the albumenising of the block, for if there happens to be any water on the wood, the cutter cannot produce a clean picture. One is therefore beset with difficulties as soon as work practically begins. Recently we have been experimenting once more in the matter, and this time we have laid aside the albumen printing method, and employed the carbon process. The former involves steeping the wood in liquids two or three times, and if the surface has warped in the slightest degree after sensitising, then it becomes impossible to set the contact between the cliché and the wood block, any undue pressure simply resulting in the fracture of the glass plate. It was impossible, we found, to apply a film of collodion or rubber dissolved in benzol to the wood surface first of all, in order to protect this from the action of warm water when it came to the development of the carbon print, for although, when dry, a good enough film is produced over the wood, it invariably gave way as soon as it came into contact with hot water. It was desirable, too, that the wood-block should be whitened a bit in the first place, and when either of these liquids was applied after a little powdered chalk had been rubbed on, the adhesion was less perfect than before. Next, gelatine was employed with the chalk, and alum added to make it insoluble, but the result was a film of too decided a character, although very fair image was secured in this way. A better result we were enabled to get by using a paste made up of fine chalk and sizing preparation, that sold by Newman, of Soho Square, being the particular material we employed. This white paste was rubbed well into the wood, and, when perfectly dry, brushed off with a soft brush. In this way the pores of the wood were filled with particles of chalk which were cemented in by the sizing, the latter, moreover, protecting the wood when put into warm water. A bit of carbon tissue that had been impressed under a cliché was swollen in cold water, and then pressed against the wood-block thus treated, and after a few minutes the image was developed in warm water as usual. The result was a perfect image upon the whitened block, which seemed to have been rendered impervious to water by the sizing and chalk applied to the surface. There was, moreover, no film to interfere with the cutting, and retouching subsequently with the artist's pencil over one or two flaws was a matter of no difficulty. In our case, it was a foreign woodblock that had to be reproduced, and therefore the cutter experienced no difficulty in cutting, any more than in the case of the original, except that the reproduction being a little smaller, the lines of the picture were somewhat finer. On development the pigment lines appeared thicker than they should be, but on drying they diminished in a great degree.

The New Foreign Fellows of the Royal Society.—If the Royal Society have not this year selected any Fellows connected with photography from among scientific men at home, it has honoured several foreign gentlemen of distinction, whose names are household words among us. There is, first of all, that veteran in photographic science, M. Fizeau, of the French Academy, whose name has been associated with our art ever since the days of Daguerre. Every novelty in photography, or memoir concerning it, that is presented to the Academy of Sciences, is almost, as a matter of course, first of all referred to M. Fizeau for his opinion, for no one knows better than he what is new and important in photography. Then comes M. Janssen, who, it will be remembered, discovered, simultaneously with Mr. Norman Lockyer, the fact that the protuberances of the sun can be seen during solar eclipses as well as during an eclipse, and who, for the past five years, has headed the French expedition that has been making spectroscopic and photographic observations of an astronomical character. During the siege of Paris he escaped from that capital with all his scientific apparatus in a balloon, proceeding to the Mediterranean to undertake an observation of some importance. Another new Fellow of the Royal Society is the German chemist, M. Kirchhoff, whose spectrum work is world-renowned, and he was one of the first, in conjunction with Bunsen, to draw up a concise spectrum table. Another German chemist of note, Kekulé, is also included in the list.

Absolute Alcohol.—A method of preparing absolute alcohol has been recently suggested by Mr. J. L. Smith, in the Chemical News. Photographers are aware that commercial absolute alcohol contains more than 98 to 99 per cent.; and the fluid of this kind is easily procured by basting up a litre of 94 per cent. alcohol with 120 grammes of freshly ignited lime, at intervals, during the period of a week. The lime is allowed to subside, and the alcohol will then be found to contain about 98 per cent. If really absolute alcohol is required, a further treatment with lime is necessary, another similar quantity of the freshly prepared material being added and shaken up as before. When the alcohol is basted a second time, it will be found to be absolute. The method may be a little tedious, but if absolute alcohol is required, it is as simple a plan of securing it as can well be devised.

PRACTICAL PORTRAIT PHOTOGRAPHY.

BY WILLIAM HEIGHWAY.

Chapter III.—The Negative Bath.

The silver baths, both "negative" (that in which the collodionized plate is sensitized) and "positive" (the bath for sensitising the paper for printing), are often found to be very troublesome; but generally to those only who, too indolent or stupid to endeavour to obtain a proper acquaintance with its properties, are ignorant of its constitution and chemical action; to these—and let us hope there are few such among our readers—the negative bath is a constant nightmare, and brings them to the confines of distraction. When it is "out of order," as it usually is, if it can ever be said to be in order, its disorders are extremely varied in character, and vexatious to the operator, who is at a loss as to the cause. One operator finds his bath addicted to that unpleasant habit of "fogging," and of this alone there are several species—an universal veiling of the plates in lights as well as shadows, though
of course it is not so perceptible in the former as in the latter; and in some cases entirely obliterating the image on the plate, or only a partial eclipse in the shadows. The bath of another worker may produce negatives too thin or weak, or with not sufficient contrast. A troublesome deposit, causing minute holes in the negatives, called "pinholes," is also another sign that the bath is out of season, or that the operations have been driven to the verge of insolvency by dreadful streaks and stains, the which they knew not how to get rid of! None can be entirely free from these visitations at times, but the operator of intelligence can generally determine the cause, when it is easy in most cases to remedy the defect.

One of the most fruitful causes of trouble in the negative is taken away by the bath, however to state before, in having too small a bath-holder, by which severe loss is suffered in many ways. In the first place, it can only be worked a short time before it gives signs of becoming disordered. Secondly, as it is out of order, it must be renovated, and this entails time wasted, trouble and loss of silver in pouring from vessel to vessel, in boiling and filtering, and therefore this loss has to be made up by the addition of new silver and this is sure to disturb the harmonious working of the bath, and entails on the operator the horrors of continual uncertainty. The fourth, and by no means the least, objection to a small bath, is the fact, that it is likely to get out of order at any moment, and at just the moment when you want it most. It may be said, with great force, that the smallest loss of silver is worse than very large; but with a bath of good size (say three gallons) you can calculate with some degree of certainty by the amount of work done. It may be further urged that a new bath should be ready to take the place of the disordered one, and is equally necessary with a large as with a small bath. Very true, but as a new bath is never as good as one a little older, it is often found that the same bath is the better. A silver bath continues to improve up to the very moment of its decay. A small bath is soon overcharged with iodide, the source of "pinholes" galore.

Need more be said? Are time and temper, worry and anxiety, nothing? If economy were in question it would be another matter, of course, because for a few shillings and a piece of wood we can construct a bath of a size that is able to contain the whole of a large bath, and in this case even economy is on the side of the large bath. The larger the bath, the less change is there really in its constitution, and consequently the more certainty of working is assured.

To Make the Negative Bath.

Dissolve, in the bulk of water you require, nitrate of silver, until the hydrometer when placed in it marks thirty grains. One-half of this solution should then be poured into another vessel, and iodized by adding to it ten or twenty grains (according to the quantity of solution) of iodide of potassium or ammonium, when it will be found to turn to a milky colour, and a slight precipitate may be observed. Filter the uniodized solution, and into this clear solution filter the iodized portion. Observe this order of procedure, because by reversing it and filtering the uniodized portion last, it takes up from the filtering paper the surplus iodide left behind from the iodized solution, and the consequence is an approach more or less closely to a fully iodized bath, a thing you do not, of course, desire. This bath should be quite clear.

If you do not require to use this bath at once, it should be placed in a clear "white" glass bottle, and placed in the light and sun. It should first be ascertained whether the solution is acid or alkaline: if acid, blue litmus paper will turn more or less acid, according to the amount of acid in solution, and litmus ammonium should be added to the solution carefully (shaking the bath to mix it thoroughly after each drop of ammonium added) until the silver solution, on being tested with litmus paper, shows no trace of acid; that is, when blue litmus paper does not change colour, and red paper changes to the colour of the blue paper. It is safer, in using liquor ammonia for this purpose, to put a few drops in an ounce of water, by which means you have more command over it; also, in the operations of adding ammonia or acid to a bath, it should be thoroughly mixed up before testing or adding more, or you are likely to overlook the change.

The bath, slightly alkaline then, is placed in direct sunlight, and after a short time it will grow black and inky, organic matter being in solution, and afterwards deposit this organic matter as thick mud at the bottom of the bottle, while the solution will become clear as crystal. This should then be filtered quite clear, and can be acidified with nitric or acetic acid. In the choice of acids there is some difference of opinion, some operators inclining to a preference for nitric acid, others never using anything but acetic acid for this purpose. I cannot say that I ever detected any difference in the baths made up with these two acids, but I have generally used nitric. It can be said in favour of this, that if a new bath shows signs of acidity in its first state as silver and water, it will most certainly be from the acidity of the silver salt, thus denoting the presence of nitric acid, and it seems reasonable that that acid should be the one we choose; and, too, the same acid is liberated in the bath from plates coated with red collodion, containing free iodine.

A perfectly neutral bath can scarcely be said to exist, chemically speaking; but if it is what is generally called neutral or slightly alkaline, the application of the developer to the plate sensitized therein will fail to bring out any image, or it may make its appearance for a few moments, and will be immediately covered universally with the deposit known as "fog."

The effect of acid in the bath is to decompose any organic matter present in the solution, as well as to oxidize any oxide. The acid is taken out of the bath, place in it a piece of blue litmus paper, which will of course turn red; now drop in cautiously, in the manner described in making the bath, a few drops of liquor ammonium; this throws down a blackish precipitate—oxide of silver. Be careful to stir the solution on each addition of ammonium, that too much be not poured in; the gradual change of the litmus paper back to its normal colour being your guide.

Care should of course be taken to guard against the entrance of foreign substances into the bath solution, as many are fatally antagonist to its photographic action. Of those in use in the dark room: iron (the developing agent) and hypochlorite of soda, or cyanide of potassium, are especially to be guarded against.

HYALOGRAPHY AND ITS APPLICATION TO PHOTOGRAPHY.

BY JOSEPH LEITOLD, OF LISBON.

The art of etching glass is no longer new, for among others Professor Böttcher and Dr. Braunsie was given much attention to the subject many years ago, and as these gentlemen found that the characters etched on glass could be multiplied by printing, they gave to this branch of industry the technical name of Hyalography. But very few disciples followed these two experimenters in their labours, as, indeed, is not to be wondered at, seeing that the graphic arts at that time were not in such a forward state as they are at the present day, when they are used in every connection.

Böttcher and Braunsie were quite aware of the perfect uniformity presented by a mass of glass, and the great advantage it therefore possessed in this respect over copper and steel for etching purposes. They prepared a sketch upon a polished glass plate which had previously

---

*Photographic Correspondence.*
been covered with the same preparation as that used for copper, and having bordered it with wax, poured upon it the clear fluid from the vessel, which was allowed to act upon the plate for several hours, until the lines were sufficiently deep for printing. The etching liquid in this case was made by placing in a covered vessel of platinum or lead some powdered fluor spar, and pouring upon this the necessary quantity of sulphuric acid, diluted with twice its volume of water. After mixing well, the clear fluoric acid at the top is separated, and this can be added to the vessel as needed, for etching may be etched either with concentrated acid or acid vapour, both plans having special advantages. In the latter case the vessel in which the sulphuric acid and fluor spar is contained is warmed moderately, and at the same time the etching is being done, the etched surface is covered with a sheet of paper, which is removed when the etching is complete, when the plate is ready for printing. The printing blocks produced in this way are flat and smooth, while those secured by means of acid appear polished.

In the State Printing Office at Vienna, as also in Domdorff's establishment at Frankfurt, impressions on glass have been produced in this way for the last twentyfive years. Very great difficulties have been found, however, in printing from such plates, as the glass is always in danger of springing in the printing press. Of course it is not possible to print the more delicate forms of engravings, but in this case the peculiar characteristics of glass engraving disappeared, and, as a consequence, no doubt, why the art of photoengraving is but little cultivated. By applying photography to the art, however, we think that a new impetus will be given to this important industry.

It is known that in France—and, perhaps, elsewhere—plates for fundamental purposes have been produced by means of photography and the etching process. If such productions as these are not altogether suitable for printing (they are not, of course, intended for such purpose), it is quite clear that the photographic negative plate, if submitted to a proper etching process, presents no difficulty for use as a printing block. Six large plates are now in our hands from a French establishment, which are intended for window ornamentation, and upon which, it appears, landscapes have been printed by means of photography, and subsequently etched in. The half-tones of the photographic pictures are wanting in these plates, and they seem never to have been etched in at all. The action of the acid has made a grain which renders the lights and shadows most perfectly.

In making a photographic cliché taken from a picture which has been reproduced by lines and dots, the operation is a much easier one. When the plate has been properly intensified and fixed with quicksilver and chlorides of platinum, it withstands perfectly the subsequent etching with dilute fluoric acid. M. Scaunon has given valuable directions in his handbook of heliography (St. Petersburg, 1872) for preparing photographic plates for etching. M. Auel, of Cologne, who has adopted a similar process of etching photographic reproductions of line-drawings, has shown some fine results, which were produced with much certainty. We believe, indeed, that to M. Auel belongs the honour of having been the first in Germany to apply photography to the art of halography.

Plates etched on glass in this way have a very delicate, but, at the same time, neither a soft nor warm appearance; they are, in fact, as cold and transparent as the material in which they are produced. If transferred to the lithographic stone the impressions lose their cold, glassy appearance, but then, again, a large proportion of the purity and delicacy of the glass engraving is lost.

THE PRACTICAL PRINTER IN AMERICA. XXIII.

FIXING BATHS AND FIXING PRINTS.

As has before been written in one of the preceding chapters, the prints need a fixing agent to remove all traces of the silver in them. This fixing agent used is hypophosphate of soda, and a bath of it is made of a certain strength by dissolving this in a quantity of water, and the prints are immersed therein for a number of minutes. Cyanide of potassium is never used in fixing the prints, although it is sometimes used in fixing the negatives. The reason of this is because it spoils the beauty of the tones, bleaching the prints fearfully, and on the whole is a miserable fixing agent to use for delicate photographs.

There is a diversity of the etching among photographers about the strength of the fixing bath, some using it much stronger than others do. I myself am inclined towards having a weak bath, and fixing a longer time than what I would with a strong bath, as the action will be more gentle, and on the whole better results are obtained by doing so, and blisters and bleaching are, in a great measure, avoided. It is very important that the hypo bath should be made up every time you require its use, as old hypo baths are very injurious to the prints. Take a two-gallon bottle, and place in it about one pound of the hypo crystals, fill up with water, shake well, and label this bottle "Sat. Sol. Hypophosphate of Soda," and when you have made it saturated, you are then ready to make the bath as per formula given below. To be sure that this hypo solution becomes saturated, make it up by boiling it, and let it cool for two days before you wish to use it. Just before using, shake the contents in the bottle for about two minutes.

When you wish to make the bath, take of—

| Sat. sol. hypophosphate of soda | 1 ounce |
| Water                        | ...     |
| Sat. sol. bichromate of soda  | 1 ounce |

Large quantities in proportion. Make it up in a dish which is kept expressly for this, and this alone. The bichromate of soda is used in the fixing bath for the purpose of making alkaline any free acid there may exist in the solution. This is very important, for in case the solution should happen to be acid, it would finally be the means of liberating sulphur and forming sulphide of silver, and it would deposit itself on the prints, affecting them seriously in look, tone, and permanence. Aqua ammonia is sometimes used for the same purpose, but if it is to be used, only a few drops of it are necessary, as any more will cause the albumen on the prints to become very tender, giving a nontransparent appearance to the whole print. The prints may be easily torn when the ammonia is used to excess, on account of the softness of the paper. On the whole, I think it better to use bichromate of soda, as it is, as before said, a much milder alkali than ammonia. During the cold months of winter, and also at all times when the water is cold, the soda solution should be heated to about a lukewarm state (no more), as the action of freezing hypophosphate of soda solution will be very slow, and also injurious to the prints, causing innumerable blisters all over the prints.

An assistant should pass the prints from the wash tank, a number at a time (so as to get them in as near as possible at the same time), and place them in the hypo bath (without touching the hypo solution with the fingers, which will cause the hands to get discolored). The operator at the hypo bath should separate and cover them with the solution as soon as he can, for if this is not done, and the prints are fixed imperfectly, they will then have mottled yellowish-brown spots all over them which have been laid together, and which are very observable when washed and dried. More about imperfect fixing, &c., at some future time.

After you have had all the prints placed in the bath, then note the time by the clock. Keep the prints in constant motion while in this bath, and do not allow one single print to stick to another, even for the space of ten seconds, if you wish to have them properly fixed. Too much attention cannot be given to this little thing if you wish to have your prints fixed evenly, and not have them come out, when a.....finished, full of darkish-brown spots, yellow stains, &c.
An old or porous collodion is a necessity. I am quite sure that I can attribute many of my early failures to the want of a suitable collodion. The sample with which I succeeded best was supplied to me by Messrs. Roux and Co., of London, and the negatives now before you were taken with this collodion. Messrs. Roux and Co. call it "D," or special bromo-iodised collodion. It had been in my possession for some ten years, when poured upon a plate had a very slight tendency to solidify like jelly. To this collodion—in quantity eight ounces—I added two ounces of newly-iodised collodion, and then to the whole ten ounces I added two grains per ounce of powdery pyroxylene and one grain per ounce of cadmium bromide. I found the collodion to be exactly what I wanted—namely, of a creamy consistency when poured upon the glass plate, and after immersion in the nitrate bath, giving an even, white film like opal glass.

As regards the nitrate bath, it should be forty grains to the ounce; and here let me state that the larger the bath the better, more even, and reliable will be the sensitive plates. Any bath of the requisite strength which gives a clear wet-plate negative will do for this process. The time of immersion is a matter of four minutes, and lengthening, or shortening, will only make a weaker negative.

From the silver bath the plate is transferred to a bath of distilled water, and then rinsed under the tap for half-minute, after which it is ready for the preservative, which is made thus:—Procure three bottles, which label Nos. 1, 2, and 3. In No. 1 bottle place the whites of four eggs, or a relative quantity of Thomas's dried albumen, which answers admirably for this, and in each add four dreams of liquid ammonia; in No. 2 bottle five ounces of plain beer; in No. 3 bottle five ounces of beer and ten grains of pyrogallic acid.

Take a quarter-ounce of No. 1 and the same quantity of No. 2, which mix together, and then pour over the plate, on which allow it to remain half-minute. Then wash the plate under the tap for a quarter of a minute, after which apply half-an-ounce of the preservative, which allows to drain without washing the plate, and the latter will then be ready for the drying-box.

I now come to the development, which is the most important part of the process, and with which, I believe, many persons have failed, as I did myself when first trying this process. I was under the impression that consider-.

The glass plate requires a substratum, the cleanest and most efficient being a solution of gelatine, which is made thus:—

| Gelatine | : | 75 grains |
| Distilled water | : | 90 ounces |
| Ammonia | : | 1 ounce |
| Alcohol | : | 1 |

It is better to place the gelatine in twenty ounces of cold water, and when softened, to add forty ounces of hot water.

I have tried albumen as a substratum, but prefer gelatine as it is free from specks, and enables the collodion film to adhere to the glass so tenaciously that a strong stream of water will not injure the film; neither does it injure the bath, as is the case with albumen. I apply the solution with a Blanchard brush.

THE BEER AND ALBUMEN PROCESS.

BY T. CLARK.*

Your Secretary suggested yesterday that I should prepare and read a paper on the result of my experience with the beer and albumen process, particularly with reference to those points which require the greatest care when testing this process for the first time, and for the want of which knovnowledge has been continually during my early trials.

This process was first introduced by Mr. W. H. Davies, of Edinburgh, and is much used by the members of the Edinburgh Photographic Society. Subsequently, however, Captain Abney published a somewhat different formula in the early part of last year, and having tried both formulas I may state that my most successful results have been obtained with that of Captain Abney, to which in future I intend to adhere, and my remarks will accordingly be directed principally to that modification of the process.

The glass plate requires a substratum, the cleanest and most efficient being a solution of gelatine, which is made thus:—

* A communication to the Liverpool Amateur Photographic Association.
In developing, first rinse the plate under the tap, then flood with half-ounce of pyro- solution No. 1, after which add to the same solution two drops of ammonia solution No. 2. When detail is free of burr, wash the plate, and apply half-ounce of pyro-solution No. 1, with six drops of solution No. 3. To the same solution afterwards add two or three drops of silver nitrate until density is acquired. Wash and fix in a solution of hypochlorite of soda containing one ounce of soda to six ounces of water. It will probably be found necessary to intensify with pyro and acid silver after fixing, with which any amount of density can be obtained.

I may here state that before the last application of acid silver I drench the plate with a solution of iodine and potassium, which prevents stains and keeps the shadow bright. It is composed thus:

<p>| | | | |</p>
<table>

<td>1 pint</td>
</tr>
</tbody>
</table>

So far as my experience goes, these plates do not require any backing, the film being sufficiently opaque to prevent reflection.

You are, no doubt, aware that the recent scientific expeditions undertaken for observing the transit of Venus were supplied with plates made by this process. The results have been, I understand, in every way satisfactory. I may also state that these plates are rapid. The negatives on the table were taken with an exposure of one minute in a comparatively dull light in the afternoon, the lens being Dallmeyer's whole-plate double-doubled with a half-inch stop.

I must say, in conclusion, that I can confirm all that Captain Abney has said in favour of the process, and I certainly prefer it to any other I have tried, both for reliability, perfection of result, and the comparative ease with which the plates can be prepared.

PRACTICAL SUGGESTIONS ON RETOUCHING.

Some capital hints of a practical kind on retouching various kinds of negatives appear in our Chicago contemporary, the *Western Photographic News*, from which we quote as follows:

The Negative of an Aged Face.—It is difficult to determine just how much modifying and removing of wrinkles is allowable in retouching negatives of this class; but certain it is that much more of it is done than is consistent with a correct likeness of the original. Let nature be the guide. Only the lines and shall find in a correctly printed photograph not a natural line, but a work upon it with a retouching instrument, that needed more retouching to make the shadows light enough than anything else. If an operator makes such negatives as a rule, we must conclude that his knowledge of the art is very limited, or his materials for the work exceedingly poor. To the retoucher I would say, you have a sorry task to perform, and the usual directions contained in these papers will, I fear, not be to your very much, as they describe the treatment of negatives likely to be made under more favourable circumstances.

Slightly Blurred Negatives, from whatever cause (either the moving of the subject or the focussing of the instrument), show no dividing line between the lights and shadows. As a consequence, to remedy this defect, the contrast must be made more distinct with the pencil. To do this, first draw a sharp line just where, had the negative been a perfect one, there would have been a distinct line of light next a dark shadow. Work upon this line until it becomes blended with surrounding parts, leaving the dark side as sharply defined as necessary to produce a proper effect. This method is particularly available in bringing out the features more perfectly. For instance, the sharper division of the nostrils, and a decided point of light upon the tip of the nose, are necessary. The upper eyelid must be sharply upon its lower edge and the upper edge of eye, though the difference between the white of the eye and iris much more distinct; also the light of the eyes within the iris may need a decided touch. The edge of the lips, and the slight shadows about the hair, and must receive attention. The forehead and chin must be made to come out sharply from their surroundings at their very highest points of light. Of course it would be manifestly improper to draw a sharp outline of the face, or any outline of the face, or any feature belonging to it, around the entire outline. These sharp divisions are only allowable upon the nearest points of light. As the face or feature recedes, it should be correspondingly softened about the edge, and dimmed in point of light. The careful study of a perfect negative, lighted nearly the same as the one to be retouched, will be a sure and safe guide for the placing of these shadows, and even at that the direction of the pencil can rest assured that it is possible to double the value of a negative of this kind; if care and judgment be used in following the above method.
WHAT TO DO WITH RESIDUES.

One of the perplexing questions which the photographer in a small way of business finds it difficult to answer is, What is the best mode of dealing with residues and waste solutions, so as to recover the value of the precious metals they contain? It is wrong to the interest of the photographer to let anything of value go away; it is troublesome to recover the metals when only small quantities of material are to be dealt with, especially in inexpert hands; and the inexperienced photographer is entirely in the hands of the refiner if he save his residues to send them for sale or to be reduced. We believe, in most cases, he may trust the refiner safely, and that he will take his best care of the metal, not, as will be seen, always. We have published from time to time very simple methods of recovering the silver from various kinds of wastes, whereby from fifty to seventy per cent, or even a still greater proportion, of the original silver employed may be recovered without much trouble or expense. But even the simplest of these requires some experience and some appliances to carry out successfully, which a few refiners could not always provide, with little assistance, present difficulties. Our frequent advice to such inexperienced photographers has been to throw down the silver, and send the precipitats to a refiner with every facility for reducing them, rather than risk wasting time and material in unsuccessful attempts themselves. But another difficulty from time to time occurs, of which an example has just been brought under our notice, from design, or accident, the refiners’ estimate of the value of the precipitates forwarded appears to be singularly inadequate. In the case to which we refer, a correspondent divided a quantity of residues into two equal parts, and sent to two different refiners. The amount received in return from one was little more than one-third of the amount received from the other. A remonstrance brought another remittance, and a further remonstrance a still further remittance of cash, the total amount, however, still remaining far short of the amount forwarded in the first instance by the other refiner. Here is our correspondent’s statement of the case:—

"DEAR SIR,—Will you tell me how to get the most money for my ashes, &c., if there is a convenient method of recovering the metal by myself? Because I am not satisfied with the rate of what I have sent to the refiners. I use about half an ounce suspended in the tub, precipitate the silver, &c., from the hypo solution. I then filter through felt and dry in the oven, and pound it to powder, and then burn it over the fire in an iron pot that I use to burn my cuttings, that it may be thoroughly dry. I have been allowed 6d. per ounce for forty-four ounces. The cuttings, filters, &c., I burned over the fire in a large iron pot. I received 1s. 6d. per ounce for sixty-seven ounces. I trim all my prints before toning, &c., and use thirty-five grain bath.

"The first lot of ashes I ever sent to the refiner’s I divided into two parts, twenty-nine ounces each, and hypo residue thirteen ounces each part, and sent to two refiners, whom we will style A and B. A sent me £3 5s., and B £1 7s. I was careful to mix well the ash, that it should be the same quality, if possible, all through. I wrote to B and told him he had made a mistake, and sent me the money intended for another person, as I was sure my ash would yield more metal than he had allowed for. He answered he would make two more parts, and sent me to two refiners, whom I wrote to say that after two more careful trials, he finds he cannot allow me more than £1 18s. I wrote again, and told him I had sent a like quantity to another refiner, and the result. He answers that he has again made two more careful trials, and cannot allow me more than £2 for it; and if I am not satisfied, I can have my waste back by paying him for his trouble. 

"I think photographers ought to know how they can be cheated. I was then using a sixty-grain bath, and he wanted to give me 27s. for twenty-nine ounces of ash and thirteen ounces of precipitate. I remember, when in a situation in London some years ago, I had precipitated the silver, &c., from the hypo in the same way for my employer, and he received not only the amount per ounce, but also the weight of the metal, the quantity of gold it contained, and allowing for the same.

"Allow me to apologize for troubling you.—Yours faithfully, ASHES."

There might be several explanations offered to meet the case described; but we fear that none of them would be regarded as probable or satisfactory. It is barely possible, if not probable, that refiner A made a mistake and remitted too much, whilst B remitted too little. The discrepancy between twenty-seven shillings and sixty-five shillings must certainly have resulted from a serious mistake, or something else equally serious. It is not, however, to discuss the possible mistakes in assaying, or in estimating fair profits of an individual, that we now refer to the matter. Our correspondent’s case may be that of many, and our aim is to obtain a statement of experience from other readers as to their dealings with residues, either in assessing them at home, or in forwarding them to refiners. In large establishments we believe the system of reducing the residues at home is carried out with satisfaction; but we shall be glad to obtain, if possible, comparative results of reducing at home and sending to the refiner’s, and especially to learn the experience of amateurs and portraitists conducting private businesses, who have systematically recovered the silver from wastes, either by reduction at home, or through the aid of the refiner.

IMITATION IVORY MINIATURES.

In M. Liebert’s new work entitled La Photographie en Amerique, there are instructions as to the preparation of coloured paper pictures which appear exactly like well-executed ivory miniatures, and which are especially noticeable for the freshness and clearness of their colours. The process is a simple one, and requires less trouble than the ordinary method of tinting by means of water-colours. Steinbach paper is allowed to float for three minutes on a bath of—

| Filtered water | ... | 1 litre |
| White gelatine | ... | 24 grammes |
| Iceland moss in paste with sugar | 10 | " |
| Chloride of ammonium | ... | 12 " |

The back of the paper is marked with a pencil so as to be recognized. After drying the paper is kept in a portfolio, where it will remain good a long time.

The sensitizing of this paper takes place on an ordinary
silver bath made up to fifteen per cent. strength, and when the paper has dried, it should be used forthwith.
The printing is done by means of a vignette, the image being toned, fixed, and washed as usual. When it comes out of the washing trough, and before it is dry, it is strained upon a wooden frame, and as soon as it has dried in this position, it is coloured by means of water-colours. The picture is then placed on an even surface that is heated underneath with a spirit lamp, and the back is rubbed over with melted white wax. As much as possible of the wax is afterwards removed with a flannel, and when no more can be rubbed off, a sheet of straw-coloured drawing-paper is placed against the print, the paper being backed up by a piece of wood to keep it flat. Finally the picture is put into a passepartout of patent plate glass, with a gold border, or framed in any other suitable manner.

Thus finished and mounted, these pictures appear very clear and fresh, and have all the characteristics of a miniature painting executed upon ivory.

---

TO MAKE OVALS OF ANY SIZE.

A simple and old-fashioned mode of striking an oval without the aid of instruments may be useful to many of our readers. The method, which, we believe, is known to most workers, has been so many years familiar to ourselves, that we should scarcely have thought of describing it; but a recent conversation amongst a dozen educated men on the subject showed it to be so little known, that we determine to repeat it for the benefit of our readers. The diagram was recently given in the Scientific American:

To make an oval, tie together the ends of a thread or string. Two pins arranged within the loop, as shown, govern the size of the oval, which is marked upon the paper by means of a pencil carried against one side of the loop as indicated. The dimensions of the oval may be made larger or smaller, as desired, by enlarging or diminishing the size of the loop. Elliptical mounts, mattes, masks, &c., may be accurately made in this way.

---

LIGHT A MECHANICAL FORCE: MR. W. CROOKES' REMARKABLE DISCOVERY.

BY W. T. BOVEY.

The great Sir Isaac Newton gave utterance to no idle lament when he likened his truly wonderful performances in the arena of science to a child gathering pebbles on a seashore, whilst a boundless ocean of unexplored mysteries stretched far out beyond the horizon before him; for, however richly endowed with mental gifts a man might be, his most strenuous efforts to gratify his cravings for knowledge develop the fact that a long lifetime spent in such labour only succeeds in exposing the vastness of his own and all other men's ignorance; that matured knowledge, although uppered by much thinking and patience, is, as a rule, the immediate offspring of those unlooked-for accidents called chance. A lamp swung to and fro as it hung suspended from the cathedral of Pisa; and Galileo, as he curiously watched the oscillations, obtained therefrom his earliest ideas concerning gravitation. An apple fell from the bough of a tree; and Newton was thus inspired to complicate the world which Galileo had begun. These and a thousand other instances, on record, of a similar character, prove how slight an impetus is needed to direct an observant mind in the way of progression; and yet how faltering must necessarily be the footsteps of every earnest explorer, because of the experiences of that past where theories, which at the time of their conception were conceived in the work which crumbled into the rottenness of error and oblivion at the withering touch of some newly developed truth; and it is not impossible (nay, I hold it as a doctrine more than probable) that Mr. Crookes has struck a death-blow to a portion of a belief we have inherited concerning the nature and constitution of solar optics. From Newton's day even down to the present time, solar light was and is religiously regarded as a make up of composite rays, viz., heat, light, actinism; or, as represented by colour, red, yellow, blue. The prism, by analysis, has betrayed the latter fact, whilst the thermometer and photography are regarded as faithful supporters of the former proposition. The eye has seen, the mind has cogitated, and is satisfied.

Habet, down with the thumbs. Why seek further knowledge? Each solar ray possesses its specific chemical, physical, and heating qualities, calculated with mathematical exactness; and modern opticians will bend you a ray of light into very curious angles. Surely, these being accomplished facts, our present knowledge of solar physics cannot be aught but perfect." To reasoners who would give expression to thoughts such as I have imaginatively quoted, I would say, science is the resultant of reason, and reason is too often a misguided sophist, which twists through a wilderness of doubts ere it succeeds in elucidating absolute facts. Our present views concerning the nature of light might dovetail in with practically demonstrated phenomena. They are, however, too abstruse, too complicated, too full of inconsistencies, to harmonize with the beautiful simplicity observed by the Maker of all things in the arrangement of His marvellous, and in many respects incomprehensible, works.

It is given to men to see the internal economy of nature's machinery in brief glimpses; hence the reason why that the stages of knowledge are separated by a span of years. Newton in his day was privileged, and the world was thereby enlightened. Since Newton's time others have gone out over the same ground, and modified ideas from time to time have thus been obtained—notably, the undulatory theory. The theory was based by Descartes, in a form adopted by Huygens, Euler, and our own able countryman, Dr. Young; and, in reference to the discoveries of these and other explorers, it is worthy of note that whilst they have handed down a missing link as a legacy to philosophical thinkers of the present, they succeeded in laying down truths which no future discoveries can destroy; hence we hail the advent of Mr. Crookes, not as one who will remove the landmarks we cherish and love, but as one who points toward a more perfect knowledge, inasmuch as his clever invention provides a reasonable clue which, followed up as it will be by rendezvous minds, will ultimately extract facts from inconsistencies, mysticism, and involuntarily-conceived doubts.

Briefly, the wonderful little engine to which I have more than once referred in my prelatory remarks, and which has so thoroughly succeeded in puzzling our savans of science, might be described as a marvel of ingenious contrivance, consisting of a glass tube having a bulb blown at one end, which is completely exhausted of air by means of a Deringer air-pump. Within the bulb is mounted in vacuo two light straws that cross at right angles, with a circle of silver painted at each of the four arms or extremities, one face of each disc being blackened, the other left white. On exposing this little machine to the action of light, the
arms revolve more or less rapidly, according to the nature and intensity of the light, which, for the first time, is seen to possess some mechanical force; and as the tiny engine whirls its marvellous rounds, science, with feelings of astonishment, looks on, and is sorely perplexed to account for the cause of its unlooked-for phenomenon. And is it not on account of the temporary bewildertment referred to, that I with much diffidence venture to step upon the platform to give some description of a matter that has provided me with material for observation and meditation for many a year. With no other laboratory than that of my mind, with none other guide than my own observations, it is possible that I have arrived at erroneous conclusions; but, as the final finding actually accounts for the motive power visibly developed by Mr. Crookes' machine, I am encouraged to hope that my recital might be read with some interest, even though doubts may be raised concerning the accuracy of my views.

When I first embarked in my calling as a photographer, I made it a subject of searching inquiry, and by unseasoned study I endeavoured to understand the theories, both chemical and optical, which had been written upon and accepted by the most distinguished men of that time. No doubt I still retain my early dissatisfaction with the accepted views relating to actinism, insomuch as my practical observations detected inconsistencies which the standard works on what I will term chemical optics could not explain; as, for example, the solar rays, when at their brightest and strongest, were sometimes almost entirely void of summer-like actinism, whilst at other times, when the thermometers averaged 60°F, the actinic power was at its maximum of vigour. At first I attributed the change to an absence of moisture in the paper, but on pushing my inquiries I found that similar experiences had befallen clever workers with the camera and wet plates. I then commenced a series of observations on the effects produced on persons of nervous temperament by the presence or absence of actinism, and duly noted the influence exerted by light on flowers and plants. It would weary my readers were I to describe the tortuous track pursued by my thoughts ere I reached a final conclusion. I will therefore at once to the point, by explaining the heterodox views which I arrived at, in spite of my wish to be loyal to my earlier impressions.

To make a clean breast of the matter, I must confess that I discarded belief of the tri-coiled light, as it did not meet with my practical experience, nor, in my mind, was the idea in keeping with the beautiful mechanism of creation. I could not realise a lively faith in the existence of distant planets, eternally frozen up in a lifeless torpidity, induced by a thousand times intensified cold; nor could I believe in a sun which capriciously shoots forth its rays without constancy of quality, now weak, anon strong in chemical power; in short, this seemed too much of random. I tried hard to reconcile these discrepancies by following up the accepted belief concerning invisible and intermingling mists, but extended observation convinced me that, under all conditions of atmosphere, the variations of actinic force were apparent. Hence I at length placed actinism under a less distinguished category; and in lieu of it being a direct emanation from the sun, I now recognise it as a resultant, which owes its force to its antagonism to the solar ray proper. And now to dovetail this idea with other and generally accepted theory.

That which philosophers describe as ether I regard as a normal electric fluid, which encircles the earth, and, like ozone, is changeable in quantity. This fluid, in a state of quiescence, is latent; in other words, cannot be detected by the presence of electric charges. The sun, however, excites this fluid, being repellent to each other, and such antagonism would naturally create undulatory movements. And on the rapidity of these undulations depend the intensity of heat and of light. My proposition, therefore, is that—

1st. The yellow ray is the true solar light. 2nd. That the red ray is the result of undulations of inconceivable rapidity, which develop heat, and ultimately change to uncombined electricity.

The blue, or violet, subject to a less violent agitation, is excited without losing its combined qualities, hence electrical force is developed, which lessens as the waves of motion grow slower at the edges, and in this proposition is accounted for the phenomenon of chemical force being found beyond the visible rays, as perceived on the violet end of a spectrum, whilst the idea of an existing repulsion would give some reason why those violet rays are known to extend further in length than others.

Now, if we take the views as I have faintly—perhaps imperfectly—propounded them, we at once can find some explanation why chemical force is often at its weakest when the solar rays are most powerful; and, further, we are not at a loss to understand why plants turn their leaves towards the sun, as such leaves are peculiarly sensitive to the attraction of free electricity. Nor shall we be unable to account for the reason why the dandelion opens so wide its petals when sunshine is full upon them. All yellows or less repel the chemical rays, whilst transparent substances of that colour give free passage to the free electricity; and here we have an explanation why yellow glass protects the chemical classes tinted with the colours just described, is reported as behaving in its working just as I in theory had expected; and it was not until I read that description which followed the earlier report given in the Telegraph that I mustered up courage to pen these lines. On meeting the question now entered upon to our esteemed Editor some three or four years ago, he evidently considered at the time that had not arrived for the propounding of my theory. But as the marriage service states it concerning wedding, "for better or for worse," so I, having during my scientific career been wedded to the pages of the News for better or for worse, therefore select those pages as a fitting medium whereby I might, without loss of character, bear the basting which I fully anticipate after publication of my present heterodox disclosure.

I might add that my views are entirely consistent with and are explanatory of those dark bands which constitute the phenomena known as spectrum analysis. But with this matter I may not now deal, as I fear I have already gone beyond my usual trespass on space.

PREPARATION OF GLASS FOR NEGATIVES.*

Glass plates are in general use as a basis for collodion pictures. In some places—America, for instance—sheet iron is employed in the practice of ferrotype, which is covered with a coating of permanent varnish, and then serves as a support for the collodion picture; and there are rare instances of waxed cloth being used in a similar way. These latter are known by the name of pantypes, and have the advantage that they are very rapidly produced; but they are not likely to take the place of pictures produced upon paper by means of glass negatives.

The choice of plates for the negative process is not an easy one to make. We require them to possess a certain amount of resistance against chemicals, and this power of

* Photographische Werke-Blatt.
resistance is not always present. Glass has naturally a hard film or skin upon the surface, and, on grinding, this horny crust is removed, and the softer material underneath laid bare. For this reason patent plate, which is often chosen by reason of its uniformly flat nature, is more open to attack from chemical solutions than the ordinary crown or plano-concave plate, however, red, and covered with cases. No solution or even water, should be allowed to dry upon the surface. Sheet or Rhenish glass, besides little imperfections upon its surface, possesses a certain curvature extending throughout the plate. We are in a position, however, to render this curve innocuous, even if we cannot remove it. If, for instance, the hollow surface is employed for the collodion, the curve of the glass is somewhat remedied, when the negative is put into the dark slide, by the pressure of the spring. But as the focus of an image, especially when a portrait lens is used, is in a curve, the form of the glass plate is well adapted to the reception of a sharp image. In the case of smaller plates the question of curvature is of little importance, because of their limited dimensions; and for this reason it is seldom that this plate glass is employed. When, however, large pictures have to be taken, or plans and maps have to be carefully reproduced, then patent plate must, as a general rule, be employed.

New glass requires to be thoroughly washed, first in acidified water, and then in ordinary water. Glass that has already been employed must be first of all freed from the varnish and collodion films upon it. This is easiest done by steeping in a concentrated solution of soda. In one or two days the films will be perfectly soft, and the glass is then transferred to a second bath made up of:

- Commercial nitric acid .... 1 part
- Water .......... 1

Or, what acts more energetically still—

- Bichromate of potash .... 1 part
- English sulphuric acid .... 1
- Water .................. 15 parts

A period varying from six to ten hours is sufficient to free the plates completely from all organic matter. The plates are then washed, the edges, especially, being thoroughly rubbed with a linen rag. It is a good plan, indeed, to file the edges of the glass, before it is used, with an old file, so as to make them more easy to handle, and to provide for the collodion adhering more surely to the plate.

The plates are placed upon a drying-board to drain, and are then dried with a cloth, and are ready for polishing. This may be done in many ways, alcohol, tripoli, or old collodion being used for the purpose. The best polishing material is, without doubt, that mentioned by Professor I. Vogel. A few drops of ammonia are put upon a plate, and this is rubbed over with a linen rag, a second rag being afterwards used for the purpose. In this way even dirty plates may be cleared at a pinch.

In order that the silver bath may be kept pure and uncontaminated, it is always well to keep the back of the plate perfectly clean; and to ensure this a cleaning-board or cloth should be used for placing the plate on. After this the plates are ready for coating with collodion, for only dust particles will be found resting upon the surface—easily removed by the application of a dusting-brush. A polished plate, however, it should be borne in mind, will only remain good for four-and-twenty hours, and after that period should not be used without being polished a second time. For this reason many coat their plates with a protective solution of albumen, or gutta-percha, or some such material; and in this case there is no need for so careful a polishing in the first place. Indeed, the albumenizing of a plate may be undertaken immediately after the last washing. The water in which the plate has been finally rinsed is removed by pouring over a little distilled water, and the albumen solution is then applied twice running over the surface of the glass. The plate is afterwards placed to dry. If there is no object in saving the labour of polishing when a preliminary coating is used, but the operator only desires to get ready a provision of clean plates for after use, it is well to polish the glass surface in some degree, and then to apply the albumen solution by the aid of a broad camel's hair brush. In this way you prevent the back of the plate becoming coated with albumen, and thus contaminating the dipping-bath. Plates coated with a film of albumen are dry in a dozen hours, if left in a suitable locality free from dust, and may then be collodionized, or, if needed, kept for twelve months before they are used. One great advantage of employing an albumen substratum is the circumstance that old and almost worn-out plates may be used again if thus protected by an albumen coating.

The albumen solution is made in the manner following. Fresh white of egg is mixed with an equal quantity of ammonia, and then beaten to a stiff froth, after which it is covered up and allowed to stand. In a few hours the fluid portion is poured off into a bottle for preservation. Of this one part is taken, and mixed with two parts of distilled water; the whole is filtered, but in such a manner that the solution is allowed to run down the length of a glass rod, as otherwise air-bubbles would infallibly be formed. The concentrated solution may be kept for weeks, and can be used, even if it does not smell altogether sweet. It must be filtered, however, when used, and should afterwards be thrown away. Sometimes it happens that the liquid in which the albumen has been dissolved, and of this solution a little of the albumenized plates have been kept in a damp place. If any phenomena of this kind are observed, the plates must be washed, and albumenized once more.

The coating of glass plates with gutta-percha solution is exceedingly simple. One part of raw gutta-percha is dissolved in ten parts of collodion solution. The solution to this part is dissolved with one hundred parts of light benzine. This liquid, when filtered, is poured upon the washed and dried plates in the same way as collodion, and five minutes after the operation the plate is ready to be collodionized. Unfortunately, when the solution happens to be a little too strong, or when certain kinds of glass are used, the film of gutta-percha is apt on drying to come down very thick, and to become a gutta-percha substratum. M. Scharwachter, of Berlin, however, who was one of the first to employ this kind of substratum, has now used it for a considerable period, and with much satisfaction. Before applying the collodion, all plates, whether treated with albumen or gutta-percha, should be carefully freed from dust, by passing over them the dusting brush very lightly. Lastly, it is scarcely necessary to mention that all photographic glass must be as free as possible from imperfections, and should be of a soft nature.

PHOTOGRAPHING THE INVISIBLE.*

At a meeting of the Vienna Photographic Society held a short time since, there was read a communication from a photographer at Innsbruck, in which he stated that a portrait of a lady had been secured, showing spots over the face and hands which were not visible upon the model at the time she was posed. The sitter a few days afterwards became covered with smallpox marks, and these corresponded with the spots upon the negative.

We are not in a position to enquire into the truth of this appearance, but we must here say, it was claimed that a portrait of a lady had been accidentally photographed a day before she fell ill of the smallpox. Upon the face in

* Photographische Mittheilungen.
the picture were many spots which were invisible upon the
original at the time of the pose, but which became very
prominent the next day when the disease broke out.
Dr. Vogel then remarked that perhaps photography might
be employed in obtaining a diagnosis of a patient under
some circumstances.

It is unknown to us whether any use has been made by
the faculty, or any experiments conducted to clear up this
point, but the matter seems to us worthy of investigation,
for the very surprising accuracy the photographic film reproduces details which are scarcely per-
ceptible to the human eye.

We remember, for instance, the case of a Berlin photo-
grapher who, in copying an old map, found a lot of little
dull white spots with dark margins, whose presence could
not be accounted for by any defect in the photographic
process. The circumstance that these spots appeared in
every negative in exactly the same place led to the discovery
of the cause of the phenomena. The original was very care-
fully examined, and there were found a large number of fine
yellow spots that were scarcely visible to the naked eye,
and these corresponded to the positions of the spots upon the
negatives.

M. Ebrard, who found this out, remarked that a year or
previously the same experience happened to him. He had
to take a landscape picture which, among other things,
included a white building. On the negative there was
plainly to be seen writing of some kind upon the whitewashed
wall, while, at the same distance from the original,
nothing of the kind was observable. It was only when
you approached very near to the house that writing was perceptible in most characters under the whitewash.

In Italy, indeed, the camera has been used to good
purpose by making use of this special feature of photo-
graphy. Old oil paintings have been copied on purpose
to find out the places where they have, at later times, been
painted over, it having been found that the photographic
lens is a much sharper observer than the human eye in this
particular way.

The Library at Brussels possesses a rare manuscript, of
which a large portion has faded away, and has been unreadable for the past three centuries, so that in its
present condition the MS. is very incomplete. The French
Academy was asked to assist in deciphering the faded
pages, but this learned body had to give up the task
in despair. Finally, the idea struck the authorities to have the document photographed, and behold! the camera revealed what had not been seen for generations past.

A similar observation was made by M. C. Silvy, at the
time of the London Exhibition of 1851, when that gentle-
man copied the "Manuscrit Sforza." This MS. was so
pale that the characters were scarcely to be recognised;
but on being photographed the writing came out quite
clear and legible.

The value of photography, therefore, in aiding to
decipher faded prints is obvious, and the services rendered
by the camera in this way deserve to be borne in mind.

ELECTRICITY AND THE PHOTOGRAPHIC IMAGE.

BY MAJOR FLORIDA DUNAS.†

I AM thoroughly convinced that everything sets in nature by vibrations, and that the result produced upon the sensitised collodion film by an object exposed before it is brought about by vibrations which the object produces upon the collodion. In my opinion all caloric, electric, luminous, and magnetic effects are produced by the differences of intensity, or direction of the vibrations, of one universal agent, which may very well be that which we term electricity.

Without entering at length into any theoretical exposition

† Read before the French Photographic Society.
Your correspondent has chosen North Devon for a few weeks' summer tour. Well do I approve of his choice. For soft and delicate beauty in lanes, slopes, and dells, as well as the bold and rugged grandeur of its coastal scenery, it immeasurably surpasses the South of Devon. I state this from personal observation and experience. A large number of these places I have photographed. Stand on the cliff of Ilfracombe, and listen to the music of the ocean, and watch the delicate rays of the setting sun striking on its creakes and caverns of rare beauty. From thence pass round the rocky bend of Morte Bay, with its bold and bluff cliffs of massive grandeur, to Westward Ho! There stand in wonder and admiration, as you must, on that long ridge of pebbles, thrown up as a barrier to the Atlantic rollers as they come up angry and unbeckoned to spend their strength on its ever shifting slopes. Away far out in the Channel, hanging as a soft hazy cloud in a summer sky, is Landy Island, almost a terra incognita to photographers: teeming with wild and weird granite rocks. Far down in the bend of the Bay, looking like a long silver thread, is the massed mass of Lynton and Lynmouth. Has not heard of its sylvan retreats of singular beauty? Poets, artists, and photographers have alike vied with each other to make known its charms. Beyond a jetting far into the Channel is the broad shoulder of Hartland Point, against which, almost every winter, some noble ship has been dashed and shattered to pieces. Happily, during the past winter, the breakwater has passed to pieces. Happily, during the past winter, the breakwater has passed, which it is hoped may avert similar catastrophes.

From the above points, a few miles inland, any photographer, to be busy, would have not only weeks of work, but months. I would recommend, as two good central spots, Westward Ho! and Ilfracombe. Say a fortnight's stay at each place, would enable any one to get a good many negatives of the choicest bits of North Devon scenery. Westward Ho! is a new and rising watering-place, and has many charms of its own. From thence Appledon, Bideford, and up the Torridge to Torrington, each of these are within easy distance, and all have distinct points of interest of their own. Then Clovelly can be taken, Hartland Abbey, Hartland May, and the Point, as well as the rocky coast scenery. Ilfracombe has many charming bits of its own. From thence go round to Lynmouth, which is one of the most beautiful sylvan retreats that can be imagined, where every bend and turn forms a picture. Having pointed out the route, I will proceed next week to point out the spots of greatest interest worth photographing, interspersed with a few practical hints.—I remain, sir, yours respectfully,

Dear Sir,—If you think the following will be of any use to "W. A. C. A.," please publish it.

I think as good a place as any in Devonshire is Lynton, some ten or fifteen miles north of Barnstaple. Quite near are the Valley of Rocks, Waters Meet, &c. The scenery is magnificent; here you have the sea, forests, mountains, and waterfalls all at hand. If you wish to live well, there are many good hotels; but if reasonably, a very comfortable little halting-place, very conveniently situated, called the "Cottage Inn," can be found at Lynn Bridge, about half a mile before arriving at Lynton.—I am, dear sir, yours truly,
B. F. Q. R.

PAPER NEGATIVES.

Dear Sir,—Referring to William Brooks' letter, mentioning that he had been taking paper negatives for some two or three years, I think it will be within your recollection that in the last year or two, I have taken some photo-silk banners of large dimensions; and as I was then working photography on textile fabrics, I beg to say that all these were printed from paper or calico negatives, and I have still one by me that measures six feet by four feet—rather large and expensive if taken on plate glass. Mr. Blanchard, as I understood him, only brought forward the method or adaptation as one worthy of greater publicity, and not as anything particularly new, and I can assure all my friends, and would add one word, and that is, when only one or two copies are required from a paper negative, there is no necessity to print it so dark, and waxing may be dispensed with altogether, the only caution being to keep the negatives and the sensitive paper dry.

Referring to another subject, will your able correspondent Mr. George Willis kindly favour me with fuller details of his method of obtaining the develop as described in the present Year-Book page 68? I presume 120 grms. of sulphate of copper is intended, not 120 ounces. Also whether they require 20 to 30 minutes exposure, or 20 to 30 seconds. I have not been able to obtain any successful result with the latter exposure.

In conclusion, sir, permit me to thank those correspondents who have so kindly forwarded me samples of nitro-glycerine in response to my last communication.—Yours truly,
G. Hooper.

68, Caunbury Park, South, N.

Proceedings of Societies.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The monthly meeting of this Association was held at the Free Public Library, William Brown Street, on Tuesday, the 26th ult., Mr. W. Atkins, Vice-President, in the chair.

The minutes of the former meeting were read and confirmed, and Mr. E. Twigge and Mr. Ed. Whalley were elected members of the Association.

A vote of thanks was unanimously passed to Mr. F. York, Mr. C. Dawson, and Mr. Knott, the success of the lantern exhibition at the popular meeting being mainly due to their contributions and assistance.

A number of Mr. F. York's lantern slides were handed round, the subjects being very amusing—groups of children, &c., taken from life.

The Secretary recommended the members to try and produce similar pictures. The ingenuity displayed in grouping together with their novel and characteristic, would render them more interesting than the usual photographic work.

Mr. Thomas Clarke then read a paper on "The Beer and Alburnum Process" (see page 220). The paper was illustrated by several whole-plate negatives and transparencies, showing the excellence of the process, and the vote of thanks was afterwards passed to Mr. Clarke for his paper.

The Rev. G. J. Barker exhibited some of Burgess's gelatine plates which he had exposed and developed that morning. He had had them for two years, and they showed their keeping qualities by developing perfectly clean and well.

The Rev. H. J. Palmer said that, finding he could not get intensity with the rapid plates prepared by Mr. Kennett's gelatine emulsion, he had written to Mr. Willis, of Scarborough (who had been so successful in taking interiors with them), asking him if he would undertake to give his method of development for the benefit of the members. Mr. Willis kindly replied, stating that he found no difficulty in getting any intensity, provided that the plates were first placed for five minutes in a solution of twenty-five grains of bromide of ammonium to a pint of water, and afterwards in plain water previous to development. He (Mr. Palmer) found Mr. Willis to be right, and he would strongly advise the members to try the process, which was a very easy one when mastered.

Mr. Atkins showed two stereoscopic transparencies mounted with glass coated with the varnish-collodion opal backing. There was one drawback with them—the transparencies had to be reversed, or the picture had to be looked at through the backing. He (Mr. Atkins) said he had no difficulty in obtaining an even film if the mixture were well filtered and the glass free from dust.

The Rev. H. J. Palmer exhibited and explained the method of working one of Mr. Edwards' graphophone cameras, which he
(Mr. Palmer) afterwards presented to the Society, and for which he received a hearty vote of thanks. It was decided that there should be an excursion to Lymn on Wednesday, the 12th inst., and the meeting shortly afterwards adjourned.

Talk in the Studio.

DR. VOGEL’S DISCOVERY.—A long letter by Mr. Stillman appears in the last number of Nature referring to Dr. Vogel’s discovery as to the actual value of adding certain coloring matters to a film of bromide of silver to render it sensitive to the usually non-actinic rays. Mr. Stillman recalls the non-success of various able experimentals in repeating Dr. Vogel’s experiment, and suggests that such results as have been obtained may be due to other causes. It is scarcely necessary, however, to remark that many negative results in a new and comparatively little understood direction prove nothing. Further facts and repetition of the experiments under strictly test conditions may be required, which Dr. Vogel himself may be able to supply. His recent pressings engagements in connection with astronomical photography, and his absence from home in connection with the recent eclipse expedition, must necessarily defer his immediate attention to the subject.

MUSIC FOR SITTERS.—A correspondent of our Philadelphia contemporary suggests music as an aid to successful portraiture. He says:—“Volumes have been written how to manage our customers, but little has been said of the power of music in obtaining happy expressions. I have often wondered at it, and would like to draw the attention of my photographic brethren to this fact. Everybody is influenced by it, and while you are listening to a well-known and familiar air, the time of the sitting seems to be only half as long, and the awkwardness of the situation is forgotten. Shakespeare says:

‘The man that hath no music in himself,
Nor is not moved with concord of sweet sounds,
Is fit for treasons, stratagems, and spoils;
The motion of his spirit is black as night,
And his affections dark as Erebos;
Let no such man be trusted.’

I leave it to my ingenious brethren how to administer it (piano, good music-box, &c.), and if they then, in spite of it, get a customer with savage looks, say, with Shakespeare, let no such man be trusted—make him pay the whole in advance.”

CAMERA-OBSCURA ON THE RAILWAY.—An American paper says:—“Among recent curious inventions is the application of the camera-obscura to a railroad car, imparting to the travelling and wondering beholder a moving diminutive picture of the country through which he is passing.”

FAINTLESS PHOTOGRAPHY.—A Danbury photographer promises to revolutionize the business by the introduction of a gas which renders the sitter unconscious during the taking of the picture. He has already issued cards announcing “Photographs in all styles taken without pain.”—Western Photographic News.

To Correspondents.

A LADY.—Various methods have been adopted to give a high surface to carbon prints, and amongst others varnish may be employed; but the varnished surface is by no means really pleasing to an artistic taste. The plan of enamelling as applied to albumen prints may be employed if you like the highly glazed surface. Mr. Blanchard recently described a method which he has found successful. It consists in burnishing the surface by means of a Weston burnisher. It is important in such cases, to adopt two precautions: one is to use the burnisher very hot without too much pressure, and the other to dry each print before the fire immediately before burnishing, as the material of the image so readily absorbs moisture from the atmosphere, that unless it be so dried it is apt to be injured in burnishing. If you wish to try burnishing, an ordinary negative varnish may be employed, in the same manner as it is applied to a negative. When the prints are developed on a piece of plate-glass they retain a fine surface after transferring.

HOPES.—It is probable that the distilled water was not absolutely pure, a circumstance by no means uncommon. Your best plan will be to neutralize the bath by means of carbonate of soda; pour it into a dish and submit it to the action of nitric acid until you get two, or a few days if you can spare the time; then filter carefully through pure cotton-wool, and try again. We do not like the plan of iodinating by means of a collodionized plate, although it is very commonly used. A much better method is to titrate with tincture of iodine is better in our experience.

A SUBSCRIPTION.—The irregular lumping film and morocco-like texture may arise from two or three causes. The presence of too much air in the drying of the bath is a frequent cause; but, from your description of those employed, they can scarcely be so in your case. The same result will arise from an unsuitable sample of pyroxylene. Samples made at a low temperature, giving a thin film of plate-glass when very few grains to the ounce are used, are apt to give the coarse irregular film. This tendency is much increased by the sole use of cadmium salts. The same collodion salted with iodide and bromide of ammonium would probably give a better film, especially after a little ripening, which rapidly takes place when alkaline salts are used. When cadmium salts only are used a sample of cotton made at a high temperature, giving a limp collodion and powderly film, should also be employed. Age may improve this, or mixing with a sample of old collodion giving a powdery film.

S. B. M.—Developing by means of a bath of iron solution, and fixing a bath of copper solution is very common. But it is advisable to use potassium iodide, and not be uncommon. We have frequently used such baths when producing collodion positives. But they both possess disadvantages. For developing negatives the bath has the disadvantage of diluting the plates of silver on the plate, and to this extent not secure intensity, which depends much on the presence and reduction of the free nitrate on the plate. Some skillful operators use a dish for developing. The dish is made up of small portions of plate-glass round the edges of plate-glass of the required size. In this case the dish being shallow, only just sufficient iron solution is used, and the extreme dilution of the nitrate is thus prevented. If you wish to use a dipping bath, take care that it is shallow, so as to avoid the use of a large quantity of iron solution. Remember that its developing strength is reduced by the immersion of every plate, and that it will require the frequent addition of fresh iron solution. The chief disadvantage of the use of a cyanide bath is, that it gives off fumes of hydro-cyanic acid, which are unwholesome. If the cyanide is used very weak, and kept covered up, there is no great danger. Watchfulness must be used, as, if the plate be left too long in the bath, the image will be attacked, which is not the case when using hypo in a bath.

P. R. G.—We have no means of hearing of giving you the information you ask. Almost every professional enlarger has his own mode of working; but whether in the cases you mention, development or direct enlargements; or whether enlarged negatives are used, we are not able to say with any certainty, of course, whether they will be permanent or not; but the presumptiion is, that proper care is used. For mounting such pictures nothing is better than glue.

BRISTOL.—By adding ammonium to your bath you have precipitated a portion of the silver as oxide, and left the solution weak and alkaline. Your best plan will be to add sodium carbonate, and to add a trace of nitric acid, if you wish to use a dipping bath, take care that it is shallow, so as to avoid the use of a large quantity of iron solution. Your bath will then probably work all right. For experiment you may as well try this method with a portion of the bath first.

P. M.—Waste of intensity may result from many causes. Your bath may be too weak, or not of order. Are you using a new sample of collodion? The use of a thin collodion or a new collodion is a frequent cause, especially when the film appears thin and not creamy. In this case, the addition of a thick collodion, or the addition to each ounce of a grain of soluble cotton will aid you.

VENATOR.—Many thanks. We shall have pleasure in publishing the description in our next.

T. SAWYR.—Decidedly an improvement; but you must be careful, with this lighting, not to under-expose, and so lose detail and transparency in the deep shadows.

W. BROOKS.—Many thanks. We shall look with interest for details.

ALEX. HENDERSON.—The order for 2s. 6d. duly received. The account rendered was for 2s. 1s. 9d.

PADY.—Thanks. In our next.

O. BRUCE.—We will endeavour to send some one as you wish.

P. GUTHNER.—Received, many thanks.

J. ATKINSON.—Received, many thanks. We will write to you.

L. LAWSON.—Thanks. In our next.

Several Correspondents in our next.
back again for negatives. The two chief disadvantages of glass—weight and fragility—would thus be obviated, and the travelling photographer would be made a happy man. We might have the material sensitized in rolls, in the same way as they do the carbon tissue now—a-days, and there would be no need for sensitizing and washing a number of plates every time dry films have to be prepared. This would be better even than employing the tough glass people have lately been talking about, and it would also do away with the necessity of discovering a thin, tough, transparent film for collodion support, for the invention of which the Vienna Photographic Society has offered a gold medal for the last three years. We shall have everybody turning photographers when all these improvements are made, and the advantages of alkaline development and emulsion processes will become subjects of every-day conversation.

Test Papers, and How to Prepare Them.—Some people imagine you can obtain test papers for almost every chemical reaction, and that in the same way as blue litmus paper is employed in testing for acid, so other papers stained with different materials or compounds can be secured suitable for making nearly every chemical test. M. F. Mohr, a German chemist, has lately published a good deal of information on the subject, and has enumerated the different kinds of test papers that may be found useful in chemistry, and the mode in which they are prepared. Many of these will be found useful to photographers, for there is no more simple test to be desired than the use of test papers such as these in the preparation of litmus paper the litmus should be washed with hot alcohol, Mohr tells us, and then extracted with cold water; the colouring matter thus obtained being employed for staining the test paper. It is scarcely necessary to say that the paper used for the purpose should be freed, first of all, by washing, from any alkali or acid. Turmeric roots, it appears, contain a substance upon which litmus would be affected by the action of the litmus itself, being washed in alcohol only which is affected by alkalis; the roots are washed in water until they yield no more colouring matter, and then they are treated with alcohol to extract the dye. To detect iron, Mohr recommends the use of paper soaked in sulphonate, or ferrocyanide of potassium. Bodies which act as reducing agents—such as the hypnotophiles, iodide of potassium, sulphurous acid, sulphur, etc.—are oxidized by that of potassium, and the litmus turns red. Paper that has to carry is still too heavy and breakable. We have taught our amateurs how to do with a little, and yet they grumble that they have anything at all to carry. "Now what would you have?" we asked a gentleman the other day, who complained that either he was limited in the number of views he could take in a day, or must needs have a sort of repeating back to his camera, as full of plates as the stereo-stand used for transparencies. His reply was brief and to the point. "I'll tell you in two words. Your dark slide should have a little cylinder on each side of it; in one of these cylinders place a roll of thin sensitive paper, and as you take picture after picture unroll sufficient of the paper for each negative, the paper exposed being rolled up in the cylinder on the other side of the dark slide. When the whole supply of paper has been exposed, come back, cut it into bits whose marks show position of the plate, and develop. You would then merely have to carry about with you a roll of sensitized paper beside the camera and dark slide." This was the suggestion, and although not a new one, it is one that we shall not improbably see put into practice before we are much older. Talbot's early suggestion to employ paper for the negative may, after all, come to be the process of the future, and those who have experience of it, know what charmingly soft pictures it can give us. The fibre of the paper, which is the chief difficulty that stands in the way of securing uniform prints, may, since the improvements recently made in the paper trade, be in a position to be altogether overcome, and if this were the case, the landscape photographer, whether amateur or professional, would not be the only person to welcome paper

PRACTICAL PORTRAIT PHOTOGRAPHY.

BY WILLIAM HEIGHWAY.

CHAPTER IV.

THE RECTIFICATION OF THE DISORDERED NEGATIVE BATH.

The disorder to which the negative bath of nitrate of silver is subject, when properly used, are, it may be said, simply and easily and surely prescribed for, and it is only when, ignorant of its character and the disorders to which it is liable, the operator gropees in the dark, that the work of restoration is uncertain and vexatious.

To guard against the necessity of constantly renovating the negative bath, it has been advised that a large bath-
holder, with a correspondingly large supply of bath solution, be adopted, so that it requires little attention in works of the future. As it may at any moments arrive at that stage when it is found not to work properly, another bath, in working order, should be always in its place, which you can work when No. 1 becomes disordered. A third in course of renovation may, on the deflection of No. 1, be restored and put in its place, while the disordered solution is treated in the manner to be described.

Whatever amount of silver you can set aside for the negative bath, be it great or little, or the baths with which you work large or small, depend upon it that it is much the simplest plan to have three lots of solution, one in use, a second quite ready, and a third preparing; by this plan you can never be taken at a disadvantage.

The Causes of Disorganization.——Generally, the first change in the bath is caused by an accumulation of alcohol and ether, causing a repulsion of the developer when flowed over the plate. This may be remedied in two ways:—1st, by adding sufficient alcohol to the developer to counteract the repelling influence of the alcohol and ether in the sensitizator; or, 2nd, by evaporating them by means of heat. The first method is only efficacious up to a certain point, and the presence of alcohol in the developer is not always beneficial. Place the bath in an evaporating dish over a stove until it commences to steam; air will then be driven by the volatiles, which are easily driven off.—ten minutes steaming will be sufficient. If the solution is much reduced in quantity, and the strength at the time of taking it out of the bath is not weakened (as may be ascertained by the hydrometer, an instrument by which the specific gravity of liquids is tested), the solution, by the evaporation of the water, is strengthened; there being the same amount of solution, and less water, so that it should be re-supplied by the addition of pure water, and filtered whilst still warm. This is done because iodide of silver is more soluble in a warm than a cold solution, and should any iodide be precipitated by heating the bath solution (which will only be in the case of an excess, when it is necessary to reduce the quantity), it may be filtered out in its present state; when cold it would be re-deposited. Filtered, the solution should be perfectly clear; if not, it must be filtered again.

Fogging is the new disordor to which the bath shows tendency; a mistiness, or veiling in the shadows, that in developing, instead of remaining clear and bright after fixation, there is a deposit not caused by detail, which destroys their brilliancy. Fogging may arise from a variety of causes, ascertaining which the remedy is simple. Fog may be generally classified under two heads: chemical, that caused by impurities in the chemicals; and what is sometimes termed mechanical, as light improperly admitted to the plate (otherwise than through the lens) or from dirty glass, &c.

Taking the first, or chemical causes of fog, it may be found to veil the entire plate, lights (though not, perhaps, very observably) as well as shadows. In other cases it may entirely obliterate the image. If then the fog is universal, veiling the entire plate, and it is found that it is removable by a gentle rubbing of the finger or a tuft of cotton, without harming the image and film beneath, this is chemical fog, and the cause is to be found in the colloid, bath, developer, hypo, or in the manipulation.

If the fogging is but slight, try the other bath, which, if free from the cause, will most likely show that the fault is in the sensitizing of the plate; proceed as follows: pour the solution at fault into the evaporating dish or clear bottle. If the solution is discoloured, the probability is that dirt was the cause of the fog: remedy, filter. If perfectly clear, test for acidity; if absent, add a few drops of acid. If acid, test the strength; and if below thirty grains, boil up to that strength, and filter. If after this treatment the bath works satisfactorily for a time, and again shows signs of fogging, it may be again and again restored in like manner, until simple boiling and filtering fails to remove the organic matter with which it is charged.

Under- and over-exposure, and too strong light shining on the lens, are also causes of fogging. With too short an exposure the silver reduced by the developing agent is attracted so slowly to the image that it falls on the shadows. Remedy, more time. When the exposure has been too long, the reduction of silver on the application of the developer is so rapid that the operator has not time to wash it off before the silver is attracted to the shadows as well as the lights. Of course less time is the remedy.

Temporary relief to a bath disorganized by the presence of organic matter can be obtained by adding a small quantity of a solution of permanganate of potash until the bath shows a violet colour. Place in the sun, in a white bottle, until clear, when the precipitation may be filtered out. Permanganate of potash in contact with the bath—the organic matter becoming oxidized—liberates permanganic acid, forming permanganate of silver, which remains in the bath, and is precipitated to the bottom in brownish-black flakes. The bath will require filtration and the addition of a few drops of acid after this treatment.

Temporary fogging by mechanical fogging from the chemical variations as not being universal, but formed in irregular patches, marks, &c., and not being removably except with the collodion film. The plate, perhaps, is dirty; clean your glass more perfectly. The albumen with which the plates were albumenized may not be pure; in which case see that the eggs are quite fresh, and that the solution is filtered clear. Or the cause of fog may be found in dirty fingers or plate carriers: remedy obvious.

Pinholes caused by an excess of iodide in the nitrate of silver solution are very minute, of a regular crystallized form, and are distributed evenly over the entire surface of the plate. From pinholes caused by an excess of iodide those from dust are easily distinguished, being generally larger and of irregular shape, and not scattered regularly over the plate. The causes are numerous: dust in the colloid or on the plate before collodionizing; in the bath, where the plate receives the particles on its surface; in the carrier or on the dark slide, which, on being withdrawn, sets the particles flying; in the camera, and in other ways are these kind of pinholes produced. Search out the cause, and remedy it. Those from iodide may be plainly seen on the withdrawal of the plate from the bath, covering the plate from the surface; they prevent the reduction of silver falling on the parts they cover, and being afterwards dissolved in the hypo-sulphite of soda solution, leave the fine holes or transparent spots termed pinholes. Remedy, dilution; and filtration, and strengthening of the solution by addition of silver, or by boiling up to proper strength. (To be continued.)

COLOURATION OF STATUARY.

By ROBERT N. Bow, C.B., F.R.E.S.*

The purpose of this paper is to introduce a somewhat novel mode of treatment of statuary, being a modified kind of colouration, dealing at most with two colours, and even using by preference the simple admixtures of black and white; and in order to show that this should be regarded as a very mild innovation, I may quote a few facts, and regarding the practice of the Greeks at an early time when they had attained to their highest excellence in the sculptorial art.

The two most celebrated works of Phidias, the Minerva of the Parthenon and the Olympic Jupiter, were of gigantic

* Read before the Edinburgh Photographic Society.
risé, and both composed of an immense number of pieces of ivory and plates of gold, the naked parts of the figures being of ivory, and the drapery and accessories of the metal. And, in the case of the Minerva, at least, the eyes were formed of inserted precious stones. Again, the renowned work of Polycleitus, the Juno of Argos, was similarly built up of ivory and gold; and not only were the eyes frequently inlaid with metals, glass, and precious stones, but sometimes also the lips. Colours were also frequently applied to the eyes, lips, and hair, as well as to the drapery and ornaments. It does not appear, however, that means were used to give the appearance of complexion or rose-tint to the skin, as was the case of marble statues; but it is a curious fact that this effect was by some method imparted to some bronzes even of great excellence, the works of Praxiteles and other sculptors. The gilding of the hair in marble statues was a very common practice. These aids to the expression of the simple statuary appear to have been employed more or less throughout the three hundred years during which Grecian art maintained a high position, i.e., from the times of Pericles down to the fall of Greece to the status of a Roman Province; and we may therefore well suspect that our present notions of what constitutes legitimate art in sculpture are far too restrictive.

The ancient Romans in their polychromatic work departed still farther than the Greeks from the simplicity of ordinary sculpture. They attempted to copy very closely the actual thing, by building up the statues of coloured marbles and alabasters; but we may pass over their doing as carrying less weight in questions of taste.

Owen Jones is of opinion that the Greeks used colour very generally, both on buildings, sculpture, and groups, and that even the flesh was coloured, but only conventionally, so as to avoid any attempt at direct imitation of nature.

I do not offer any arguments or opinions myself in favour of the use of a variety of actual colours even employed conventionally. But I propose to apply for the most part to every piece of sculpture; for undoubtedly there exist many beautiful statues and groups of the case of which it would be felt by all to be sinning against good taste to modify in the slightest degree their uniform white surface, or to employ any obvious device by which the eyes or other features might be more forcibly indicated than results from a pretty strict adherence to the simple portrayal of the natural thing. But I propose to apply for the most part confined to those characterised by placidity of expression, and intended to convey ideas of repose, indifference, or patience; the eye is a blank in which it is left to the imagination of the beholder to picture the appearances of intelligence, and incapable of exhibiting the side-glance of coquetry, suspicion, or alarm; or of reinforcing the expression of the eyelids in the upward gaze of admiration, or surprise, or the downward droop of reverence and humility. And it must be borne in mind that in many phases of expression the eyelid and the eyeball contradict one another in action, as in coyness, cunning, watchfulness, and horror. These the sculptor cannot render or distinguish from some of the former without marking in some way the surface of the eyeball.

Statuary is constantly weak in the rendering of the eyes. What is well modelled exactly according to nature, a very disagreeable effect would generally result from the light failing most powerfully upon the part where the pupil and iris occur, and thus rendering it lighter instead of darker than the rest of the eyeball. The usual device to mitigate this reversal of light and shade is to make the curvature of the eyeball less intense in front, securing at the same time a shadow from the exaggerated contour. The effect of the eyes was that when the expression to be conveyed is active or passionate, the absence of the positive shades of the pupil and iris are such unequivocal blinshes. It is the strictness of rendering often is still further departed from, especially by the modern sculptor, with a view to reduce the evil. This is most commonly done by drilling a hole where the pupil occurs, so as to get a deep-cast shadow as a substitute for the positive darkness, and defining the circumference of the iris by a slighter ring-like cut. Another mode of treatment is to score out a saucer-like depression as large in diameter as the iris. Now no doubt these modifications may be claimed as the work of the sculptor's tools alone; but such a pretence would be mere quibbling, for the effect is got by a direct departure from the modern sculptor's first rule of art, which restricts him to the most accurate rendering of the surfaces that the material will permit of.

But it is not in the eye alone that the want of positive shade is felt. The eyebrow even plays an important part in expression, and here also is involved the issue of light and shade, but the weakness is not so seriously noticed, since the eyebrow, though coloured, is not a mere surface indication, but has its form and position, defined both by elevation and variety of texture. In the case of the mouth, however, much of the individuality of expression depends upon the form and position of the line where the carmine of the lips joins the skin-colour; this may be strikingly shown by changing that line in an actual face by means of painting the surfaces, or by painting variously the lips of casts from the same head; it is therefore a necessary and important feature in individual likeness, and it is somewhat surprising that the device of a fine cut has not been had recourse to for marking the outline of the deeper colour of the lips: I believe it is here, even more than the eyes, that the difficulty arises in conveying the idea of likeness in portrait busts.

It might, perhaps, be possible to employ colour generally if in a very subdued manner, and under the skillful hand of a true artist, so as not to give rise to that feeling of repugnance produced by waxwork-like imitations of life. And some art-critics indeed think that Gibson succeeded in the case of his tinted Venuses.

The more satisfactory of these objections are produced by waxwork-like imitations of life are very striking, and it may be worth attempting to get some insight into its nature. Perhaps the solution should be found in this, that the art-character of the work should never be disguised, but that, along with the pleasure or interested feelings called forth by the beauty or effectiveness of the representation, there should be mingled a feeling of admiration for the art displayed in the wax replicas. Judged in such an eye, both the present and how unsatisfactory must be any attempt to produce an absolute representation of the reality of nature; for if by any possibility we were successful, we could regard the work merely as a substitute for the reality, and should miss the feeling of art-admiration, on the other hand, putting aside the impossible, the nearer we attempt to approach a verisimilitude of living nature, the defects in our work must become more numerous, more easily detected, and much more offensive, from the very pretensionness of the sham.

It may be objected to this explanation that in the case of a painting on a flat surface the work is more admired the more perfect the delusion of its reality can be carried out; but here the imposition is not of the same absolute kind, and the art-admiration constitutes a large part of the pleasure experienced. Perhaps the peculiar nature of the deception attempted in the case of painted sculpture, or waxwork figures, may be brought more clearly out by the following consideration. When we see a mutilated ordinary statue, say one from which has been broken part of an arm or leg, we do not find the statue to become repulsive; but if this same statue were painted, and treated in so masterly a manner as to represent a living form very to sory, I think it must be apparent that the statue was as I have supposed would become hideous. Now no similar feeling could be produced by a pictured figure merely mutilated by an accident to the canvas; it only presents itself as an injured work of art, exactly analogously to the mutilated unpainted marble statue.

(To be continued.)
THE PRACTICAL PRINTER IN AMERICA.

XXIV.

WASHING THE PRINTS.

The prints, after they are removed from the salt-water bath, are then to receive the final washing, which will render them ready for the further operations, such as mounting and finishing. I would here most earnestly advise all printers to allow their prints to soak about ten minutes in salt water, before proceeding to wash them, as besides saving the annoyance of having blisters on them, they will also be much more easily washed.

This washing is the most important of any of the washings before mentioned, because if it is insufficiently done, the result will be much more disastrous than any of the others. The other washings were only to prepare the prints for other solutions, and it was not so important, as the silver would finally be removed in the fixing-bath.

But in this case, when you discontinue the washing and proceed to mount the prints, they will then in the future be good, bad, or indifferent, according as to how the final washing was done. This destroying power which is so necessary to be removed is the hypo sulphite of soda, a considerable quantity of which still remains in the print.

The theory of washing is that the water gradually dissipates the hypo in the prints, providing the washing is permitted to go on long enough, and then the prints can be mounted and dried without any danger of bad results from further chemical action. The young beginner can thus see the necessity of frequent changes of water to remove this destroying agent, and hence it would be a good plan for the first half hour or so after the prints are fixed to wash them by hand, and then put to the washing apparatus, whatever that be, in small establishments this can be done by permitting the water to run into a dish at one corner. If they are so done, it would be best to do as recommended, as they are likely to be all together the greater part of the time when thus washed.

Washing by hand can be done in the following way:—

Take a suitably sized dish, fill about half full of water, and when the prints are removed from the salt water, place them in this bath of clear water with one hand, while with the other you place them under the surface. When the prints are all placed in this bath of water, then move them all about for five minutes, and then pour off the water and fill up again, and let them stay in five minutes more. Do this for four or five times more, using lukewarm water, as it will do the work quicker than cold, and then they will be ready to wash in the dish, as above described, by arranging the dish so that the water will run through and between the prints. When there are only six or eight scores of prints, they will be washed in a short time.

The great secret in washing prints is to keep them separated, thus permitting the fresh water to move between them all the time. In large batches—say twenty, thirty, or forty sheets of paper—this washing cannot be done in so simple a way as the above, hence it becomes necessary to have washing-tanks that will, on account of its peculiarly adapted make, wash the prints perfectly, and a longer or shorter time is required according as to how thoroughly the tank does its work.

To keep the small cartes from getting between large prints—say 14 by 17, and even larger ones—and thus getting imperfectly washed, a series of washing-tanks are arranged, a large one of which is intended for the washing of large prints alone, and a smaller one for the cartes-de-visite.

Every photographic gallery has some sort of a tank which is intended for this washing, and I will mention here that these final washing-tanks should never be used for any of the other operations, such as the other washings, fixing, &c.

These tanks are more or less perfect in performing their work, but there is one idea that is generally carried out in them all, and that is to have an outlet in the bottom of the tank or tanks, so arranged that without sucking the prints in, the water can be let out at the opposite side to where the fresh water is supplied.

To keep these prints in motion while washing, and thus make them "self-washing," a rotary motion is given to them on account of the manner in which the water enters the tank. A half-inch pipe generally runs along the inside of the tank, suspended midway between the top and bottom, and having small holes so made in it that the water strikes the water on the opposite side, as well as on the whole of them, and on different parts of the surface, thereby causing the water to rotate around the tank, carrying the prints with it. The tank is so made that the diameter increases as it proceeds towards the bottom of the tank, so as to prevent the prints from sticking to the sides of it; and to be doubly sure that they will not adhere to the sides, there is on the under surface of the pipe an array of small holes running the whole length of it, sending small streams of water down the sides of the tank, driving away the prints which may be there. To prevent the apparatus from overflowing, an overflow is made, which, when the water has reached that level, it can be run off without danger of carrying the prints with it. But better still are those tanks which are got up on the siphon plan, and then when the water has reached the proper level, etc., it is all let off, leaving the prints on the bottom of the tank, which is, of course, so made as to prevent any hurt coming to the prints.

A washing apparatus got up on the siphon arrangement, and emptying itself every twenty or twenty-five minutes, is one which I used in a printing-room of an excellent gallery for a number of months. It consisted of a bottom, towards the bottom, for the same reason as was stated above, i.e., to prevent the prints from sticking to the sides. The pipe in it was arranged as was described above, and the bottom of the tank was covered with small pebbles about two inches in depth, which are or should be evenly distributed. Close to the bottom of the tank, on the side, a hole was made (hid from the prints by a piece of glass, the edges of which were ground smoothly), which permitted the water to pass through by means of a little iron pipe (varnished) two inches in length, which fits in exactly close to the wood. About an inch of this pipe projects beyond the tub, and a piece of suitable rubber hose is fastened and bent in the form of a siphon, the higher level of which is fastened by a wire in its proper position. When the water in the tub has reached the highest level of the siphon, which has been gradually increased as the water will fall therefrom, and in a few minutes the tank will be emptied of the water, although there is a stream running in all of the time. The prints will be gently let down into the pebbles, and the water, after it has ceased to run out, will again cover the prints, and set them afloat before they have stopped draining. The supply water never should enter the tank nearly as quickly as the siphon carries it off when it has once started. No danger need be apprehended from the drying of the prints while the tank is filling up again after it has once been emptied. For large prints this is not very good, especially if there are a quantity of them, but on the whole it is a very good arrangement.

In large establishments the prints are generally allowed to wash all night, and if there are many to be washed it had better be so done, unless the whole of the washing is done by hand, and then a shorter time will answer.

Prints which are toned and washed Saturday afternoon should be washed by hand and mounted up before you leave the establishment for the night, as remaining in the water over Sunday will very much affect the prints; for, of course, they are not to be mounted on Sunday. In some establishments the printers do not print photographs on Saturday, but spend the day framing, making porcelains, &c., &c.

The prints should be tested before they are removed from the tanks, for the purpose of being sure, to see as to whether they are perfectly washed or not.

Dr. H. Vogel, in his "Handbook of Photography,"
boil also four ounces of isinglass, and mix the two together; place them in a water bath (glue kettle) with half a pound of white sugar, and evaporate till the liquid is quite thick, when it is to be poured into moulds, dried, and cut into pieces of convenient size. This immediately dissolves in water, and fastens paper very firmly.

Removing Ink Stains.—A solution of chloride of lime in water to which a little acetic acid has been added is among the many receipts recommended to remove ink stains from linen.

Staining Marble.—Marble can be stained different colours by the following substances:—Blue, solution of litmus; green, wax coloured with verdigris; yellow, tincture of gamboge or turmeric; red, tincture of alkanet or dragon's blood; crimson, alkanet in turpentine; flesh, wax tinged with turpentine; brown, tincture of logwood; gold, equal parts of verdigris, sal ammoniac, and sulphate of zinc in fine powder.

Mounting Microscopic Objects.—A mounting fluid for microscopic objects is made of gelatine one ounce, honey five ounces, distilled water five ounces, rectified spirit half an ounce, and creosote six drops. Filter through fine flannel. Heat the honey before adding to the gelatine, which last must be dissolved in the boiling water. When cool, add the creosote, and when it is not the least bit of it, is still present, the washing should be repeated. When we wish to test finished pictures by this method we must soak them first in water, and then test the water as described above.

Before you proceed to remove the prints from the tank let off all of the water in it, and rinse them well in a bath of clean rain-water, so as to remove all traces of the iron rust and settings from the water, which may have been carried in the tank through the supply. Rinse the prints in two or three changes, so as to get them as clean as possible, and they will be much nicer and cleaner when they are finished. When the prints are removed from the tank always rinse it, and fill up again with fresh water, and it will be ready for use next time. If the peppers are used in the tank they should be washed every day. If the tank is made of wood, then once a week or fortnight let off all the water in the morning, and dry it thoroughly, and varnish all over the tank and pipe with some shellac varnish, and you will keep the tank in better condition by so doing, being more easily cleaned in the future from settings, &c. Once in every two or three months scrape off the old shellac with a broken piece of glass, and varnish it anew. Thin and clean the tank, and in front of it, to all your tanks and sinks, for they should all be shellacked.

All of these little things help towards making fine work.

ANOTHER BATCH OF RECIPES.
We select, chiefly from the pages of the Scientific American, another batch of recipes, the majority of which will be found useful to photographers.

HYDROXYLSINCE INK.—The main objection most people have to sending communications on postal cards is that the writing is, of course, open to general perusal. A good way of avoiding this difficulty is to use sympathetic ink. A solution of ten grains hyposophite of soda in five ounces, or until the whole fuses uniformly. Take out the melted mass, and, when cold, powder it and dissolve it in boiling water.

PORTABLE MUCILLAGE.—To make pocket mucilage, boil one pound of the best white glue, and strain very clear.

WATERPROOF CEMENT FOR CAST IRON PIPES, ETC.—Take equal weights, in dry powder, of burnt lime, Roman cement, pipe-clay, and loam, and knead the whole with about one-sixth the weight of linseed oil. The addition of more Roman cement improves the quality.

CEMENT WHICH RESISTS MOISTURE AND HEAT, BUT NOT THE DIRECT ACTION OF FIRE, FOR GAS AND STEAM PIPES AND SIMILAR PURPOSES.—Two parts of red lead, five parts of white lead, four parts of pipe-clay; fine and dry, and work them into a stiff mixture. Use for mixing the parts of bright iron filings or fine chips or borings with one part powdered sal ammoniac, and moistening with urine; when thus prepared, force it into the joint. It will prove serviceable under the action of fire.

STONE CEMENT FOR THE JOINTS OF IRON STOVES.—Mix, together with finely sifted white ashes, an equal quantity of finely powdered clay, and a little salt. When required for use, add enough water to make a stiff paste.

IRON CEMENT WHICH IS INSUSCEPTIBLE TO RED HEAT.—Four parts iron filings, two parts clay, one part fragment of a Hessian crucible; reduce to the size of rape seed and mix together, working the whole into a stiff paste with a saturated solution of salt. A piece of fire brick can be used ahead of the Hessian crucible.

CEMENT FOR FASTENING WOOD TO STONE.—Melt together four parts pitch and one part wax, and add four parts brick-dust or chalk. It is to be warmed, for use, and applied thinly to the surfaces to be joined.

EXPERIMENTAL COMMITTEES IN PHOTOGRAPHY.

A point of some interest arose in course of the discussion of Colonel Wortley's paper at the Photographic Society on Tuesday evening last. In referring to the uncertainty of many modes of estimating varying rapidities, Col. Wortley suggested the importance of appointing committees of competent gentlemen, whose report, after adequate trial of suggested novelties, would be of much value to the photographic community at large, who were often bewildered by the various processes and modifications proposed in different quarters, any attempt to test the whole of which would be a hopeless task for photographers generally.

The suggestion met, however, with less favour than might at first glance have been anticipated. It was not much discussed; but after definite condemnation from Mr. Hughes, as one of the disadvantages from the Chairman, it found no champion or advocate except Colonel Wortley himself. Mr. Hughes remarked that the appointment of committees to investigate various subjects seemed to be a common practice in some foreign societies; but he could not call to mind the reports of any such committees, or any advantage arising out of them. The history of two committees appointed by that Society would be familiar to the members. In one of them, it would be seated to lament the causes of fading in silver prints; but after all its protracted and careful labours he scarcely thought that any increased permanency in prints had been secured. The other committee was the well remembered collodion committee, and he did not think that any one had heard of any good which arose out of its labours. The duties of such committees, if properly performed, would be unrewarding and thankless, and the results, he thought, of doubtful value.

That a careful and efficient performance of the duties which would devolve on such committees would be a serious tax upon the time and attention of men capable of undertaking them, and that the office would be a thankless one, there cannot be a doubt; and it is in this fact rather than in the doubtful value of the reports of such committees the chief difficulty in securing their establishment lies. It is true that the celebrated, or notorious, collodion committee was in every way a lamentable mistake. Established at a time when little was known as to the sources of excellence in collodion, it should have been prepared to examine every collodion, details of the preparation of which were submitted to it. As a practical test it examined the collodion of one manufacturer only, and, without comparison with others, pronounced this the best. The labour of this committee cost the Society, if we remember, ariht, upwards of one hundred pounds. Collodion was supplied ad libitum to the members for examination and testing, and gallons of it, we have been assured, were in existence years afterwards, in use for cleaning glass plates. The whole purpose and the action of the committees constituted one huge blunder; and its history would probably serve as a beacon, indicating what to avoid in the formation and action of future committees. In the printing community the action of Hughes was not fortunate in his illustration of inutility. If the immediate results in the shape of absolute permanency in silver prints were not as marked as might have been desired, it may be safely affirmed that the photographic community at large knew much more of the immediate causes of fading after the publication of the report of that committee than had been known before, and it is not to be supposed that mere knowledge of the causes of existence, if not absolute permanency, has been given to hundreds of thousands of prints by the information diffused in that report. It is a long time since it was published, and much experience in photography has been gained since that day. It is not improbable that another committee appointed for the same purpose, and conducting its operations with the same care, would arrive at results of great interest and value to the community.

Colonel Wortley, replying to the objections of Mr. Hughes, said that the difficulty of dealing with such extended subjects as permanency in photography must be admitted; but his suggestion was of a much simpler nature. Some one suggests, in the journals or the Society, that an addition of a certain kind—say, of nitrate of uranium—to the negative bath would secure a definitely increased ratio of sensitiveness. Three capable gentlemen appointed by the Society could determine the results of a couple of hours' experiment, and their dictum would be invaluable in settling the perplexities of the photographer who was bewildered by the multitude of suggestions which appeared from time to time. Probably no proposition could more admirably harmonize with the wishes and wants of a large portion of the photographic community than that of Colonel Wortley. What could possibly be more desirable than that every improvement in photography, every suggestion for increased sensitiveness in the plates, for greater excellence in result, or for greater advantage of every kind, should reach the non-experimental worker with credentials as to its precise claim and degree of trustworthiness, which should enable him to determine without test or experiment whether it was right or wrong? Occasionally he would no doubt think it was very good of the capable men in London who sacrificed their time and energy for his benefit. Occasionally, too, others would come to the conclusion that the reports were not very trustworthy, after all; that the members had some personal purpose to serve; that they were "armchair" or "couch," who in some occult and inconceivable manner served their own ends by devoting their energies to the public service in connection with the art they loved. That experimental committee could be of inestimable service in many respects we think might easily be demonstrated; whether it would be wise or desirable to institute them for the purpose of establishing points which must energetic and capable photographers may easily settle for themselves, and which all desiring the advance of the investigations published from week to week in the journals should be willing to test for themselves, is a question. The point out of which the discussion arose—namely, a suggestion for a committee to test a point which Col. Wortley mentioned in his paper, the advantages to be gained by the addition of nitrate of uranium to the negative bath—was one on which the report of a committee would, doubtless, be interesting; but is, at the same time, one which presents very little difficulty for verification to the intelligent photographer in his everyday practice. Col. Wortley, who, in connection with the Wohlytype process, and in connection with his own emulsion process, has experimented extensively with ura-
PHOTO-ENAMELLING.

At the last meeting of the French Photographic Society, M. Geymet called attention to his method of enamelling, and gave some further details on the subject. The sensitive liquid he employs for coating the plate upon which the image is produced is made up of:

- Water... 
- Glucose... 
- Honey... 
- Powdered gum... 
- Saturated solution of bichromate of ammonia...

No great skill is required to pour this sensitive mixture upon a glass plate. The film is dried, and is then exposed for two minutes in the shade. The image being afterwards developed by means of enamel powder passed over it with a brush. This operation should be repeated two or three times, leaving an interval of two or three minutes between each manipulation.

The film is covered with a film of solution containing 1% per cent. of pyroxyline, and when the gelatine has formed, the plate is plunged into a bath of acidulated water which contains 10% per cent. of hydrochloric acid. The plate is then washed in the first bath with some precaution, for the gelatine will be found to be soluble in that acid. After a few minutes' sojourn in this second water, the image is lifted by means of the plate, and placed in a sugar solution:

- Water... 
- Sugar...

The enamel plate, cleaned with borax, is then pushed under the gelatine, and the print is upon its definite support. The plate is put upon filter paper, which absorbs the excess of sugar solution. The gelatine is covered with tissue paper, and it is pressed, softly in the first instance, with a tuft of cotton-wool. Afterwards more pressure is used, the tissue paper being changed and the gelatine being dried. It is then placed, while wet warm, in a saucer of sulphuric acid without water, to destroy the colloidion, which happens after half an hour. Nothing now remains but to rinse the gelatine plate in two or three waters, and when dry it is burnt in a muffle furnace, heated to a cherry-red temperature. Any retouching that is necessary is done, and the lights are heightened by touching them with dilute hydrofluoric acid, and afterwards the gelatine is put into the muffle again to get a final glance. Any colouring that may be necessary is applied by means of a brush, taking care that the tints on the face and hands must be applied at the very last. Flesh-coloured tints must be burnt in with a very moderate heat.

HOW TO PRODUCE PHOTOGRAPHIC PORTRAITS WITHOUT A CAMERA.

A HUMOROUS sketch of a Chinese studio is given by M. C. Kardatz, who was one of the gentlemen attached to the transit of Venus staff that proceeded to the seaport of Tachifu, to make observations in the neighbourhood. The Chinese officials, our German collaborator tells us, marvelled much over the solar instruments that were imported to take the necessary astronomical observations, and their use was explained through an interpreter. An image of the sun was secured and handed over to the chief dignitary, who was exceedingly delighted with this sonar presented to him.

M. Kardatz was asked anxiously if he could photograph them on the earth as well as in the sky, and this he proved by taking a group of the officials then and there assembled, with which the Chinese dignitary was highly delighted. He thanked M. Kardatz a thousand times, and gave him a pressing invitation to come into the interior, to see his estate and to depict any objects he desired in the neighbourhood. M. Kardatz gave no decided answer to this polite invitation except that he would consider of it.

The reason for all this ceremony towards the photographer of the party would appear to be the fact that he brings the first camera that has yet been seen at Tachifu, which is, by the way, not an unknown spot, but the most fashionable watering place among the Southern Chinese. The doings, therefore, of our brother in the art were looked upon as miracles, and much and much more dogged and his movements watched wherever he went. Nevertheless, it turned out there was a photographic studio at Tachifu, and one, too, at which a good deal of business was conducted. You could go in at any hour of the day, providing you were a Chinaman, and get a portrait executed in a very short time. This Chinese artist, somehow, did not appear to have much affection for the novel representative of the art, however, and instead of affording a welcome in any way, he seems to have studiously avoided a meeting. His studio was considered a sort of tell-your-fortune abode, and, so it came out, did not even contain so much as a camera or a lens. The heretofore Chinese had merely acquired a large collection of portrait negatives, and when a customer came, he took his picture mentally, looked through the stock, and chose the picture most like. As all Chinese heads are pretty similar, and their piglets much about the same length, it was never difficult, apparently, to make a match, for the public were quite content with what they got for their money. The photographer seemed to thrive, for the good people of Tachifu were never tired of having their portraits taken, and, as everybody was satisfied, there was no reason why matters should be changed, although it is M. Kardatz's opinion that if a Shanghai photographer were to pay the place a visit during the bathing season he would run the heathen Chinese very hard, and, no doubt, make a lot of money.

FRENCH CORRESPONDENCE.

In reference to the process of enlargement communicated to the Photographic Society of Great Britain by Mr. Valentine Blanchard (a process which much resembles
that made known by Mr. Wharton Simpson in the Year-Book for 1872), M. Valette, a Paris photographer, informs me that for several years past he has used an analogous method, but with a very advantageous modification. He is able, by the plan he adopts, to retouch the transparent positive, which serves to secure the enlarged negative, and to change in an important manner the image to be reproduced in a very simple way. He simply stretches behind the positive cliché a sheet of vegetable paper, upon which the changes and additions are effected that may seem desirable, after he has scratched away by means of a point or eraser any spots or blemishes he desires to remove. This is a dodge which, without being very new, will be of much practical advantage to the operators.

At the monthly meeting of the French Photographic Society, which took place on Friday last, a curious document was exhibited by one of the members. It was one of the first engravings produced by Nicéphore Niépce. This sketch, which brings to mind the early essays of our art, dates from the period between the years 1829 and 1833— that is, during the time of the partnership between Niépce and Daguerre, which was terminated by the death of the latter partner. There is no need to remind my readers that the first experiments of Nicéphore Niépce were made in the direction of photo-engraving, having for their object the etching of the image traced by light upon the metal plates covered with bitumen of Judea. The subjects chosen by the illustrious inventor were stamps, or old engravings of a simple character.

M. Franck de Villescholle presented through M. Davanne a photometer of the Autotype Company of London. The readers of the Photographic News certainly know all about this little instrument, so that I need only mention the favourable manner in which it was received.

It is well known that for some years past the interposition of coloured glasses between the sensitive plate and the object to be reproduced has often been employed with success. An optician, M. Berthiot, has conceived the idea of constructing lenses with the interposition of parallel glasses of a blue colour, and he exhibited one of these instruments before the members of the Photographic Society last Friday. It appears that it is not a matter of indifference where the coloured glass is placed, and after a number of ingenious experiments he has found that the same should be fitted between the two lenses, quite close to that which forms the anterior face of the combination. M. Davanne, who has tried a lens of this character, did not find that it had a more rapid action than those of combination, but he found that the pictures were still much more intense than in the absence of the coloured glasses, even when the objects taken offered very great contrasts. M. Leon Vidal, who was present at the meeting, observed that in many cases it would be well to change the colour of the glass interposed between the lenses, and he suggested the mounting of glasses in such a way that they might be slipped in or out at will, as is the case with diaphragms.

M. Berthiot also exhibited a lens with a multiple focus, the novelty of which consists in the mounting of different lenses. The ensemble occupies a very small space, and forms a suitable pocket instrument.

M. Ribera has forwarded a numerous collection of specimens of a new matt paper, which possesses the advantages of being very economical, and preserving intact its whiteness; it is capable of giving very fine impressions, as is proved by the beautiful pictures that accompany the communication he sends. The sensitizing of the extreme paper, as it is called, takes place upon a six per cent. silver solution only, and there is the advantage that the bath never becomes discoloured. The image, being upon the surface, is easily retouched. The sensitizing bath is composed according to the American formula, which consists in adding nitrate of ammonia to the silver solution. The nitrate of ammonia is prepared by saturating ammonia with pure nitric acid, or, in other words, by mixing the two materials in equal parts. According to the quantity of nitrate of silver taken, half the same measure of this mixture is added; thus, to make up a litre, thirty cubic centimetres of the mixture are taken, and to this are added six or seven hundred grammes of water, and this mixture is added to the rest of the water dissolved sixty grammes of nitrate of silver. The whole is mixed, and then filtered. A slight addition of alcohol or of sugar is useful; it is well also to have the bath slightly acidified with nitric acid. To maintain the bath in its proper condition, which is of course necessary, it is well to have a separate bath of 64 per cent. strength, for instance, and every time the paper is used, the quantity exhausted in the actual bath is replaced by the addition of this stock bath, so that the solution always remains at its proper strength. The paper, upon which, as we have seen, very fine translucid prints may be obtained by means of the wax or varnish applied after fixing, appears to be exceedingly useful for enlargements.

M. Aime Girard made at the end of the meeting a very interesting communication respecting the production of micro-photographs, which he employs as enlargements in his lectures at the Conservatoires des Arts et Métiers. He has before the members presented an excellent method of enlarging the image in the camera, and the projection of the image upon a screen. M. Girard laid stress on the point that he did not make use of any novelty, but that he simply utilized the processes already known, and made use of them for his benefit. Thus he employs an oxyhydrogen lamp from an ordinary vertical microscope, and a camera of short focus fitted to a microscope by a tube furnished with a plane mirror inclined at an angle of 45 degrees. As a matter of course, the whole of the apparatus is properly fitted together. The focusing is easily effected by moving the ground glass to and fro, so that the grain cannot interfere with the detail of the picture. A micro-photograph was taken before the members upon wet collodion with a pose of ten seconds only. The sensitizing and development took place through the medium of yellow light of a gas jet burning with a fragment of chloride of sodium.

After having terminated the complete operation of printing upon glass a microscopic image, M. Girard exhibited to the members a whole series of photographs of the same kind enlarged upon a screen, employing for the purpose the apparatus of M. Moldein. In this way he was able to show the members a means of recognising adulterated flour, and to follow into all its details the fabrication of various articles, and to examine the most minute structure of several plants. No auxiliary is so powerful for seconding scientific instruction as the art of photography. M. Aime Girard has proved this once more by indicating to his colleagues of the French Photographic Society the importance of these pictures, which photography has taken a large share in obtaining, and which are better than the most skilful draughtsman could furnish.

To complete the account of this interesting meeting, I must mention that M. Rousselon, who reproduces every year for the firm of Goupil and Co. the paintings shown by artists at the Salon, exhibited a further series of prints illustrative of the recent progress he has made in the art of heliography. The opening of the Salon for 1875 has given M. Rousselon a large amount of work, and he has lately produced some interesting clichés. It is to be hoped that, instead of printing them by the ordinary method, he will employ his patent process, which is to prepare permanent albums, which, by reason of their artistic and historical value, will be hereafter of great importance. Durable photographs of this kind would gain admission at once to all libraries, from which silver prints are at present excluded by reason of their uncertain permanency.

Ernest Lacan.
THE ACTION OF HYDROGEN UPON NITRATE OF SILVER.

In a recent number of the Comptes Rendus appears an account of some experiments recently undertaken by M. Békét off upon the action of pure hydrogen on nitrate of silver solution. He has proved that this action is a substantial one, but slow in its progress. His experiments have continued above four months. He placed the silver solution in contact with the pure hydrogen in sealed tubes enveloped in several sheets of paper, and placed in a horizontal position in a dark locality.

M. Békét off sums up the conclusions that his experiments have led him to as follows:—

"I think I may conclude from my experiments that pure hydrogen reduces silver in the manner of other metals, in neutral or feebly acid solutions. The difference between my results and those obtained by M. Pellet seems to me capable of explanation either from the short duration of his experiments compared to mine, or on account of the solutions of silver that he made use of being too acid. As it is probable that the reducing action of the hydrogen is limited, and stops altogether when the liquid has attained a certain degree of solidity, I propose to clear up this last question in a further investigation."

The issue of M. Békét off's further experiments will be looked forward to with interest by photographers, for the subject is one that may possibly be of practical importance to them. If hydrogen can be made use of in photographic operations for reducing the time of exposure of the plate in the camera, there is no reason why it should not be employed as an accelerator in some instances. So far back as the beginning of this century, experiments were made with the gases in the camera to facilitate photographic action, Nicéphore Niepce working for some time in this direction.

Correspondence.

TO MAKE OVALS.

Sir,—One small but important omission has been made in your short article quoting from Scientific American, "To make Ovals of any Size," and that is how to determine exactly the method of using the string to give a definite size. It is this: draw a couple of crossed lines truly square,

\[ x \]

now mark half the width of the oval wanted at \( a \) and \( b \), next measure half the length of the oval wanted from these points to a point on the line \( c \), as at \( x \) these two points are the foci of the oval wanted. A very useful way to catch the string is to cut a circular notch about one-eighth of an inch from the point of a lead pencil. This prevents the thread from varying its position.—I am yours,

W. H. Davies.

DEVONSHIRE SCENERY.

Sir,—Westward Ho! is an euphonious name, and there are but few authors who have lived to see their works give a name and a township to a locality. Those who have read Caspar Kingsley's work "Westward Ho!" know what a charm he has thrown around the immediate locality of which I am writing. Almost every spot of interest he has invested with a living reality that few who have read it but long to visit those scenes so vividly depicted. Your correspondent should drop that work in his travelling case, and read it when he has time, and I can assure him many of his photographs in this district would be doubly enhanced. Whether that photograph should be the long bridge of Bideford spanning the Torridge, a scene depicted near the Bloody Corner of Appledore, the "House of the Seven Gables" at Northam, a picture of the romantic fishing village of Clovelly, or by the weird granite rocks of Lundy Island all are depicted by Kingsley with a living detail that makes one regret that a good deal of the work is fiction.

I will suppose your correspondent to take Westward Ho! as his starting point on his photographic tour. If his means are somewhat limited, he may lodge cheaply at the village of Northam, which is about half a mile from the above place. Here there is a very fine tower and church worth photographing, both the interior and exterior. In the yard he will see many a headstone erected by the kindly hands of the villagers to the memory of many a stranger who has been cast by shipwreck on the sands of Northam Burrows. He may also get one or two good pictures from Bone Hill looking towards the Bay. This spot is close by the church, and therefore there would be no trouble. He may then run up and take a photograph of the "House of the Seven Gables." Although it retains the historic interest with which Kingsley has invested it as the residence of his principal hero, yet I must confess it has lost much of its charm by being modernised a few years ago by its present or late owner. Though it retains something of its ancient form, yet its old quaintness is gone.

Westward Ho! as a watering-place may be commended, moreover, for its breezy openness, its quietness and repose, its extensive sands, its golf links, and its zigzag walks on the gorse hills, on the slopes of which are built its terraces. I consider about a dozen different negatives may fairly represent the most interesting of its scenery, and its natural objects of curiosity. There is its wonderful "Pebble Ridge," extending along the beach, terminating with a range of sand hills; its like as a geological puzzle is unknown, although something of the kind is seen at Portland. Yet, for size of pebbles—more like boulders than anything else—is unapproached in many parts of Devonshire, and extends towards the sea to a depth of near forty feet. Yet sometimes, at a high spring, and in a N.W. gale, the sea leaps over this natural barrier. Two or three good negatives may fairly represent this object. They should be taken late in the day, so as to get the cast shadows on the land side.

Two or three negatives should be taken of the "Raised Beach." These become interesting to geologists. Two or three general views from the Pier and the Ridge will also be interesting; these will be better to be taken late in the day, as the sunlight is then streaming across the gorse hills, lighting up the deep green and golden yellow (scented) but non-scented masses of flowers. Several negatives can be taken in various picturesque spots from the hills above, and the slopes, which are a fine extensive range.

Cloud effects and "scapes" no place is finer than Westward Ho! Here the breakers come up full and unchecked from the Atlantic, and, with the strong active power of light, instantaneous pictures can generally be taken in fair weather. Clouds can at any time be taken. I use a wide-angle Dallmeyer landscape lens, and can secure clouds at any time without trouble. If the sun is staring on the lens it is a good plan to use an umbrella to shade it; in fact, it is an article I always take when working out doors.

From Westward Ho! we will trudge along the clifves to Peppercombe, Buck's Mills, and then to Clovelly. Each has some exquisite bits of rock scenery worth a plate or two; in fact, the former has not been done.—I remain sir, yours respectfully.

Theo. Tredake.

Bideford May 11th.
Sir,—I notice that in your last week's issue a correspondent enquires where he may most profitably pitch his tent for scenery in this country. But to generalise as much as possible, I would suggest Ilfracombe or an adjoining village for bold coast scenery. Near, on the old coach road, there are magnificent hill views; and to visit landscapes within easy walking distance, I think anything might be found.

In another district there are Okehampton and Bedford; the latter is noted for a beautiful valley and Waterfall.

Now I want a little help myself. What is the best manner to produce skin-like texture on the face, &c., of a photo, after the style, for instance, of the "Alisee Lorraine" pictures, or of the Prince of Wales by the Chichester photographers. Yours truly? B. T. Rolls.

Aina Cottage, Lynmouth, Devon, May 7.

WHAT TO DO WITH RESIDUES.

Dear Sir,—Your correspondent "Ashes" may have been cheated in the return given for his residues, as a good opportunity offers to those not conducting their business in a fair manner to do so; but let us be charitable, as it is just probable that your correspondent's mode of precipitation would be found a source of much trouble, and uncertain, even wasteful, results in unskilful hands or by careless treatment. My own experience of refiners is (and I only deal with well-known respectable houses) that they give a very fair return for the waste entrusted to them, and my mode of treating wastes is at the service of "Ashes."

I precipitate from hypo solutions by a saturated solution of sulphur and ponceau; collect the black precipitate; wash it well; and when sending it to the refiners append a caution that it contains a little sulphur, and is likely to be inflammable.

If "Ashes" has a furnace and would like to smelt it himself, he should add bicarb. of soda, grind all together in a mortar, and melt with a small piece of borax.

The plain silver washings may be treated to salt, the resulting precipitate placed in a porcelain capsule, and caustic potash added until the whole mass acquires a black colour. Dry, and the black oxide is ready for the furnace; with the addition as for the sulphide and a small portion of nitre. The treatment of the residues is very simple, as it only requires a little bicarb. of soda mixed with it, and may then be readily melted down to the metallic state by placing it in a crucible, and adding a small piece of borax and a little nitre. A scrap of brown soap might also be added.

I think he will find that by attending to these very simple directions, he will experience no future difficulty.—I am, dear sir, yours faithfully, D. K. GRIFFITHS.

Proceedings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

The usual monthly meeting of this Society was held in the Coudert Street Gallery on the evening of Tuesday, May 11th, Mr. J. GLASHER, F.R.S., in the chair. The minutes of a previous meeting having been read and confirmed, Sir George Prescott, Bart., was elected a member of the Society.

The President then informed the meeting that Mr. Edwin Cocking had been unanimously elected by the Council as Assistant Secretary.

The Secretary read a paper by Col. Stuart Wortley on the subject of "Comparative Rapidities," which will appear in our next.

The Chairman, referring to a suggestion in the paper as to appointing a committee for the purpose of making certain investigations on the subject, said it was not made to the President and Council, but to the society or meeting; and the meeting must deal with it if they thought fit.

Mr. SPILLES, referring to the alleged fact that the addition of a trace of uranium to the bath gave increased sensitiveness, remarked that from its yellow colour it might have been supposed to possess a retarding quality, and asked if the increased rapidity were due to its fluorescent qualities.

Mr. FISHER (the Hon. Secretary) remarked that, being one of the most fluorescent bodies, it might possibly accelerate in virtue of that quality.

Mr. HARRIES said that the idea of establishing testing committees had more than once been mentioned lately. On the Continent they seemed very fond of the practice. They often heard of committees being formed for that, and the other, but he must say he did not so often hear of any results arising out of their action. No doubt the reports of such committees would be very interesting if they were published; but they might not amount to much, after all. He remembered two committees formed by this Society: one was the Printing Committee, who, after much experiment, reported, but photographic prints were, unfortunately, much more stable, and more likely to be invited to form. They had made no report, and were not likely to be thought probably each one of them had made a resolve not to be caught on a similar committee again.

The idea of such committees was doubtless an attractive one, but he doubted, after all, its desirability, as well as its practical value. In conclusion, referring to the alleged accelerating qualities of minute of uranium, he asked if there were any chance of an iodide of uranium being formed by its addition.

Mr. SPILLES said he thought not. Chloride of uranium was very soluble, and he believed the iodide was also.

Mr. W. NOEL HARTLEY said the iodide was still more soluble than the chloride.

Mr. FISHER asked if Col. Wortley made any photometric examinations of the flame of his gas burner, as it would vary throughout the day, and the hours of eight and ten at night were specified by the Act as the period when the gas should possess a certain standard of illuminating power, and at all other times it was uncertain.

Col. Wortley always commenced his measurements by such an examination, using Whistler's photometer. In relation to Mr. Hughes's objection to the Committee that the proposed were of a simpler character, and to deal with different matters to those referred to as failures. The subjects they undertook were complicated and difficult; but if A. B. affirmed that the addition of one gram of uranium to the bath gave a certain specific increase of sensitiveness, a committee of three or four capable photographers appointed by that Society could determine the question in a couple of hours; and their Aye or Nay would be gladly accepted by photographers who would be saved the perplexity necessarily involved in the publication of novelties, or guarantee, appearing in the journals. With regard to the period of uranium in the bath, to which Captain Abbey had already testified as well as himself, he hoped at some future time to give details.

The Chairman did not see that a committee could satisfactorily determine the point, as it would be very difficult to get a standard burner, owing to the varying pressure of gas.

A vote of thanks to Col. Wortley was then passed.

The Chairman announced that an exhibition would be held in the Pall Mall Gallery, to be open during the month of October and November. He also read a circular calling attention to the Belclaire Memorial Fund.

It was announced that at the next meeting Mr. Hooper would read a paper on the advantage of sulphocyanide of ammonium as a fixing agent. The proceedings then terminated.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The seventh ordinary meeting of the session was held in the Secure, the evening, the 6th inst., the President (Dr. Thomson) in the chair.

The minutes of the previous meeting were read and approved,

Mr. Bow, C.E., one of the vice-presidents, read an interesting paper on the "Colours of Sunlight." (See page 280), and illustrated his views by a number of busts and statues, both plain and tinted.
Mr. Alexander Mackay said that he had listened with much pleasure to the reading of Mr. Bow's paper. He thought the subject was a most interesting one, and he was considerably impressed by the many cases where sculpture would be largely benefited if colour could be properly laid on marble. Anyone who would take the trouble to look at a marble bust, placed in an ordinary well-furnished room, would see that it was made to look pallid and unnatural by contrast with the colored curtains, carpets, and furniture, and he had no doubt that by the judicious application of colour a bust in such a position would be wonderfully improved. He was much pleased with the effect produced by the tinting of some of the specimens exhibited by Mr. Bow, but thought the colour a little too violent, and believed that a much better result would be obtained by lighter shading.

Mr. Ross quite agreed with what Mr. Bow had said regarding the advantage to be derived by sculpture from proper colouring. There could be no doubt that in sculpture there had always been a desire for colour, and he thought it was impossible that one could be reconciled to the absence of expression given by the eye. All else might be well enough, but the finest statue that ever was made had always at least the one fault of being that of one that was blind.

Mr. Bashford thought that the real difficulty lay in getting a suitable colour or tint for marble. Gibson's Venus was, he thought, a little too strongly tinted; but he certainly, if it was possible to do it properly, would prefer a tinted bust to one without colour, especially so far as the eyes were concerned.

Mr. Heaton agreed with Mr. Bow on this point, regarding the ability displayed in this interesting paper; but he must still adhere to what he had formerly occasion to state, that sculpture should not be coloured. He believed the fundamental principle of fine art is likeness in unlikelihood, which involves to a certain extent it's being natural. In accordance with this, if the tinted portrait painter gives the colours of nature on a flat surface, and on the same principle the sculptor should give the rotundity of nature without its colours. Mr. Bow does not violate this principle when he says that certain busts or statues would have their expression more pronounced by the addition of shadow tints. But sculpture should be sufficient in itself, without adventitious aid. The "tinted Venus" showed what colour can effect, giving a voluptuous beauty to a statue, but at the same time, destroying the principal artistic and chief charm of sculpture, viz., the sort of semi-transparent spiritual effect that results when the human form is represented in the purity of white marble.

Mr. Turner thought the effects produced by Mr. Bow very pretty, and had no doubt that, for busts that were to be kept under glass, something of the kind should be attempted. However, had a doubt as to its suitability on statues that were exposed to the weather. The question was one for the chemist to grapple with, and try to discover some means of permanently stabilising the marble to the required tints.

Mr. Ward said that those who did not agree with the views expounded by Mr. Bow, he thought that much benefit would result from his and such like papers coming before the Society. Hitherto photographers had given far too much attention to chemicals and cash, and too little to matters at least equally important, and he was certain that if they would give more attention to art they would be both better men and better photographers. He moved a hearty vote of thanks to Mr. Bow for his remarkably interesting and suggestive paper, which was unanimously adopted.

The Chairman then read the following question that had been found in the box:—"What is the cause of and cure for streaks in the backgrounds of wet collodion negatives?" which elicited a somewhat lengthy and interesting discussion, in course of which it appeared that the general opinion was that the streaks were caused by condensation of ether and alcohol in the bath, or a corrosive and repellent sample of collodion. As a cure for the latter, Mr. Bashford said that he could always with the greatest ease convert a sample of tough, horny collodion into one giving an open powdery film, or at least change one that, when poured on the glass, would not partially flow over but flow across it to form a tough film on each side, into one that when treated in a similar way left straight lines only. The change was effected by simply giving the collodion a vigorous shaking, and then letting it settle.

Dr. Dyer was glad to hear of Mr. Bashford's discovery. If it was really so, one of the difficulties of all dry processes would be got rid of, namely, the difficulty of getting a suitable powdery cotton. He had long known that believers in homoeopathy had much faith in shaking their medicines, but had never suspected that it would be of any use in photography. He should, however, try it, and report results at a very early opportunity.

Mr. Bashford assured the members that there really was no doubt about the effects of a good shaking, and said that if anyone failed to get the desired result, and would bring the sample to him, he should be glad to try it.

The usual distribution of photographs by ballot then took place, the pictures being the gift of Mr. Alex. Nicol, and consisting of a lot of extremely fine portraits of children going to and returning from the well; for which he received a vote of thanks.

Mr. Tunnell, on his visiting the room, paid a welcome after his six months' sojourn in America, and we understood that he has agreed to give at next meeting an account of his impressions, from a photographic point of view, of art and photography in the States.

Talk in the Studio.

Saturated Solution of Hyposulphite of Soda.—A correspondent, Mr. G. A. Avery, calls our attention to a manifest inaccuracy in the "Practical Printer in America," by Mr. Hearn, in our last, in which one pound of hypos is referred to as saturating two gallons of water. This is a serious error, whether a slip of the pen or a printer's error. Hyposulphite of soda is an extremely soluble salt, one ounce of water dissolving hundred parts of it. As a rule it is wise, in preparing solutions, to take a definite weight in all cases rather than deal with the question of saturated solutions, inasmuch as the precise point of saturation will necessarily vary with temperature, and, in degree, with other conditions.

Fay e. KAMPMEIER.—A case of some interest to photographers was tried in the Kingston County Court last Friday. Mr. Fry, of Surbiton, sued the defendant for the value of silver cuttings and clippings of silver. Letters acknowledging the liability, and promising to pay, were placed on photographic paper and collected their residues, had callow in August last, and purchased silver cuttings, &c., and promised to remit value at once. This he had not done, although often promised.—Verdict for plaintiff, and immediate payment ordered.

"It is Finished."—The London Stereoscopic Company have just published a fine photograph of a very noble piece of sculpture, by Callier, of the head of Christ at the moment of death. The head is in alto relievo, in a circular niche, and is singularly grand and pathetical. An admiring variéty of expressions in the life of Christ, give especial interest to work which will be equally prized for its art excellence and its touching appeal to high religious sentiment.

"Spiritual Photographs" in Paris.—The Paris Correspondent of the 'Times' has the following to say on the subject:—It appears that the mediums are not only capable of calling spirits from the vastly deep and communicating with them, but that they have now succeeded in photographing them. Such is the last discovery here, and you may probably like to know how it was made. A few weeks ago a paper devoted to the spirit-world published the following:—"M. do P——, a gentleman who had thoroughly studied the doctrines of Spiritualism, manifested the desire to obtain, by means of spiritualist photography, the portraits of his parents, and especially of a brother whom he had tenderly loved. He declared a medium, and after two attempts succeeded in getting the portrait we offer to our readers to-day. The medium was able to give him that great satisfaction, and at the same time to prove to the incredulous world the immortality of the soul, and the possibility of direct relations between the departed and the living. Underneath this announcement was the photograph of M. de P——, with the image of his brother hovering over his head. The discovery seems to have taken, and in the same time the mysterious photographer-medium traded profitably on the folly and credulity of human nature. At present, however, he has gained a name among the police of having been swindled out of his money, and the medium was arrested. A search was then made in the photographer's atelier, 'and the mysterious 'spirits' were found to have turned into mechanical lay-figures."
Europe. Two almost invariable characteristics are prominent: first, that the proprietors—the ones in whose name the work goes to the public—were educated artists before they became photographers. Indeed, in nearly all cases where success has been marked, they have been actual workers under the sky". Let us notice a few prominent names. Adam-Salomon, of Paris—acknowledged king among photographers—is also a sculptor. Leescher and Felsen, of Berlin, were one or both educated and practised artists. Luckhardt, of Vienna, was thoroughly educated in all the principles of art before he gave attention to photography. Nottman, of Montreal, was originally a portrait painter, if I am correctly informed; as was also Kent, of Rochester, N. Y. And they in a few years succeeded to reputation with many others, equally capable as men, after twenty years' hard work, had failed to attain, because they lacked this art knowledge. Our Sarony, too, was a trained and practised artist for years before he entered the photographic army and stopped at once to the front. Kartz also was an artist; and Mora, who is coming on so rapidly, was educated in the art schools of Paris. All who have named are workers with skilful hand and trained eye, putting their art knowledge to practical use in arrangement of graceful 'pose,' artistic and effective lighting, suitable accessories, and controlling every possible aid to perfect results. The list might easily be extended in this country by the addition of such names as those of Rejlander, Robinson, Faulkner, Bedford, Mudd, and a host of others.

PADDY’S PORTRAIT.—A correspondent at Redcar sends us the following:—

Dear Kitty, by this you will see that I’m taken,
But not up for murder, or fighting, or drink;
It’s up in a room on a glass that I’m taken,
And faith ’tis a very good likeness, I think.

They brought me up to a room decorated
With calico curtains and rods made of brass.
I wondered to see myself so elevated,
And to find every slate on the roof made of glass.

Th’ gentleman axed me to please to keep steady;
He axed me to scrub to the back of my head,
I’m sure he thought I was intoxicated,
For that was to keep my head steady, he said.

He then put his head in a bag like a boomer,
And told me to try and keep steady awhile.
I sat all the time like a modest young woman,
Objecting to frown, and yet longing to smile.

Then he took direct aim with his lunettes at me,
I jumped from the chair crying, "Mother! you shan’t
Take my life." "Don’t be frightened," said he, smiling at me;
"It is not your life, but your focus, I want.

And then he completed his grand operation
In less space of time than a minute could pass.
It’s held by my identification;
And sure enough the was was in the glass.

A VARNISH FROM Vulcanized RUBBER.—The following description of a method of making a varnish from vulcanized rubber is taken from the Moniteur Industrial Belge. In answering questions relating to the dissolution of vulcanized caoutchouc, we have repeatedly doubted the possibility of coagulating. The present process, however, seemingly includes burning out the sulphur, &c., and then dissolving the residue. If any of our readers practically test the recipe, we should be glad to learn the result. The fragments of vulcanized rubber are deposited in a deep earthenware pot, which is closed by a tightly fitted cover, and exposed on burning coals for about five minutes. During this period care must be taken not to open the vessel, as the vapour is highly inflammable. On removal, the mass is examined by pushing a wire into it to see that it is uniformly molten; and if this be the case, it is at once poured into a large, well-laden tin pan, and left to cool. When hard, it is broken into small pieces, and immersed in a bottle with benzole or rectified essence of turpentine, and there thoroughly shaken and stirred. The dissolution then takes place, and after a brief rest the clear liquor which forms the varnish is decanted from the impurities which settle at the bottom.—Scientific American.

GOLD BRONZE for furniture is a mixture of copal varnish mixed with gold-coloured bronze powder. The last is bicalophile of tin.

DIVER.—A couple of double dark slides to carry four plates will be more portable, less trouble, and, we think, less costly, than a changing box, as from the neatness and precision in the fitting of the latter it cannot be made very inexpensively. The only ingenious alternative is an ordinary plate-box and a changing bag, in which the plates might be transferred from the box to the dark slides; but this is very inconvenient, and always involves some risk to the plates.

M. R.—It is very difficult to deal with negatives where the prints, having not soaked with rain during printing, have been suffered to dry with the paper stuck in fast contact. The adhesion is caused, of course, by the albumenized surface, which, being softened and made slightly tacky with the rain, causes it to stick fast when dry. The print cannot, of course be saved; but in a little judicious care the negative generally may. Slightly moisten the back of the print with a sponge, or by placing a piece of moist blotting paper at its back, watching carefully when the albumenized surface is sufficiently softened to admit of its release without allowing the moisture to penetrate unnecessarily into the negative film.

ZINC.—Water kept in a zinc cistern may be used for ordinary photographic purposes; but distilled water for baths, &c., should be kept in a glass bottle. 2. Good portraits may be taken with an east light; but you will have the disadvantage, during the furniture, of having to do the direct lighting.

S. CURB:RAN.—We shall have pleasure in giving our opinion, but it must be borne in mind that every such decision is but an opinion; it may be valuable, of course, as based on large experience, but no such decision is of an absolute and unchallengeable character.

M. L.—There is no such list in existence that we know of. An announcement in our pages would reach the majority.

G. B. R.—The "Holy Family," which is the copy of an old painting, is not, as far as we know, copyright. The other probably is; but we cannot state with certainty.

G. WILKINSON.—We remember to have seen photographs of the statue of Gutenberg in the city of Mainz, in the shop windows in that town; but we are uncertain whether any are procurable in this country. We have been informed that we have seen it in Mr. England’s series of Swiss stereoscopic views; but we are not certain.

H. W.—There are several modes in which wax is used in conjunction with coloured photographs. One method, which was patented by Mr. Sarony many years ago, and the patent now expired, consisted in taking a plain paper print, coloured in the ordinary way in water colours, only making the tints unusually bright. When completed, it was saturated with pure white wax, and backed with a piece of white paper. The effect, if well done, closely resembles that of an ivory miniature. Another plan consists in taking a tinted, somewhat delicate print and colouring it on the back, washing it, and then backing it with another dark print roughly but vividly coloured. We have often given details, and of course cannot repeat them very minutely here. On page 90 of our last Tran.

Photo.—We shall be glad to hear further from you. There is some slight confusion in dealing with the "furnace enamelling," as it is not, and of course could not be, applied as a treatment to paper prints.

BYRN.—Thanks. We are satisfied that much comfort and convenience would be gained by using the "Reception," and shall certainly have pleasure in recommending it to photographers.

JOHN GREEN.—Many thanks. Another correspondent had been good enough to suggest the additional information before we received your favour, and the latter was in print when yours reached us.

F. BAUM.—Thanks for details. We hope the event will be better than you fear.

G. AVERY.—Many thanks. We make the correction, as you see, in another column. The additional details you suggest also appear in another letter.

THOMAS SIMS.—Thanks. In our next.

ALBERT SCHRIBER.—Received.

J. G. ATKISSON.—Received. Thanks. Notice in our next.

D. WINTHROP.—Received. Thanks. In our next.

Received: The "Chemistry of Light," by Dr Hermann Vogel.

Several articles in type are compelled to start over for want of space.

Several correspondents in our next.
PHOTOGRAPHY IN AND OUT OF THE STUDIO.

Photography and Military Equipments—Picture Galleries for Everybody—The Hot Weather.

Photography and Military Equipments.—We have on several occasions called attention to the useful application which the War Office makes of our art in securing pictures of warlike materiel, and in recording changes that take place from time to time in equipment, in ordnance, in uniform, &c. Even alterations in the conduct of military exercises in the country, in the training of the mililary, or in the tools and mortars trained, or a pontoon bridge built—all these things are depicted by the camera, and the pictures sent far and wide, to the indies and to our colonies, wherever British troops are stationed, and wherever, therefore, the influence of the change would be felt. The manner in which men are to be equipped is also important enough to invoke the aid of the camera, for even non-military readers know what importance is attached to keeping the parade being properly and uniformly dressed and accounted for. A recent instance of the ready way in which military changes in dress and uniform can be effected throughout the army in a short time has recently been exemplified. The Adjutant-General decided, not long ago, that there should be a change in the dress and equipment of the Pioneer, a regiment stationed near London. The body of the regiment, as mentioned in our last issue, was ordered to report themselves at the War Department Photographic Establishment at Woolwich, and here, having been satisfactorily accounted for in the new style by officers appointed for the purpose, were forthwith photographed. Each soldier was depicted from the back and front, standing properly at attention, and thus a score of pictures showing what importance is attached to keeping the army perfect in uniform. The hundred and more regiments of the British Army have now ten thousand copies of each, and these photographs will now be distributed, and from a month of the order being given by the Horse Guards, every commanding officer will have in his possession a set of photographs, showing the position of every strap and buckle on each man’s uniform. Within this brief period every Pioneer of the army will be dressed as accurately uniform as if the Adjutant-General had himself superintended each individual equipment. With the corps of Pioneers, of which no two are equipped alike, from the serjeant (who is generally the carpenter) downwards, any attempt at describing the equipment in writing would necessarily be imperfect, and however elaborate the wording might be, it could never convey so good an idea as that given by a photograph. The exact place where one tool or the other is to be fitted to the waist belt, whether it is carried under the arm, or on this side or that, how the pick and shovel are to be strapped together, where the armour is to carry his gun spikes and hammer—all details of this kind, which to a non-military mind may appear of little importance, but which in the army, where much stress is laid on uniformity and discipline, are matters of material weight, are demonstrated in a photograph in the plainest way possible. This is, therefore, a very happy way of solving a military problem.

Picture Galleries for Everybody.—We see that Holman Hunt’s picture, “The Light of the World,” has been purchased for the purpose of being reproduced by photography. This is, we trust, a sign that artists are becoming fully alive to the merits of photography as a means of turning their copyright to account. In many cases it may happen that a picture will scarcely pay the expense of being engraved, while copies of it would sell very well at a moderate price; and in instances such as these the artist would no doubt make a substantial profit by having his work photographed in two or three different sizes and reproducing prints by a摄影 process at a reasonable rate. No one, it is true, cares about giving a guinea for a silver photograph that may fade sooner or later, but for handsome copies of pictures of a permanent character no one would grudge a fair price. Only a short time ago we referred to this subject, and mentioned the fact that already in Paris the pictures in the Salon (the French Royal Academy’s gallery) were being photographed, and of thousands of these prints would be distributed, and others of these copies of a large number of them. There is no reason why reproductions of this kind should not find a ready sale among the many hundred thousand visitors who flock to the Royal Academy, if only the copies were brought properly to the notice of the public, and by publishing (say) at five shillings, ten shillings, and twenty shillings per copy, very nearly half of them would be disposed of. Private galleries can be considerably reduced if they can offer these copies at a low price, and indeed the layman in the few wealthy families, we should then have the middle classes possessing their library and modest collection of pictures. The supply of such pictures would soon create an enormous demand; but, as we have just said, we must secure to the purchasers a permanent picture. There need be no interference with engravers. Such pictures as it will pay to engrave may still be reproduced in the medium of photography, and only the more expensive pictures would be the more envied. And as to piracy from photography, this would never occur to any great extent, for to photograph a painted picture well, much skill and good apparatus is necessary, and these are not usually possessed by those who occupy themselves with unlawful pursuits.

The Hot Weather.—The change from winter to summer has been so sudden this year that one cannot help thinking that the clerk of the weather has got confused and confused over the recent cold, and has been and left out the spring. Only the other day we were calling out for the hot water can to stand the developer on; now we are asking for ice to cool the collodion and other chemicals. The glass plate in the slide, if it is allowed to remain very long in the hot glass room, or leaning against a tree out of doors, is apt to get very warm, and then there is good-bye to all your developed plates. Streaks and stains are almost unavoidable no matter how skilfully you pour on the tepid developer, unless you are a very rapid worker indeed. A good cooling of the glass prior to development is obviously one of the best preventives against disagreeables such as these; and in the case of dry plates even, the development is rendered much more under control if the temperature of the glass is first of all lowered. Vessels with ice containing a bit of flannel or old blanket soaked in them, which can be conveniently wrapped round any bottles of solutions to be cooled, will be found most convenient under the circumstances, the flannel preventing a too rapid thawing of the ice, while at the same time it is handy to use.
PRACTICAL PORTRAIT PHOTOGRAPHY.
BY WILLIAM HEIGHWAY.

CHAPTER IV.—(continued).

TREATMENT OF THE THOROUGHLY WORN-OUT BATH.

After repeated partial renewals of the bath, as already described, it will, in time, from a combination of causes—as excess of alcohol and ether, of iodide and other additives—require a more thorough renewal. Proceed as follows:—

Pour the bath solution into one-fourth its volume of water, when it will immediately become "milky." In this way it dissolves more iodide than by pouring even a greater amount of water into the bath solution, because the water is greatly in excess of the silver solution during the greater part of the mixing, and the bath is so greatly reduced in volume that it cannot take up or redissolve much or any of the iodide. The bath added to the water is thoroughly filtered through two or three thicknesses of filtering paper. Filter perfectly clear.

It is to be borne in mind that the solution, which is now reduced to about twenty grains of silver to the ounce of water, is saturated with iodide, so that when the solution is raised in strength, the percentage of iodide is reduced to the proper proportion.

Pour this clear solution into the evaporating dish, and heat it on the stove until it begins to steam. Test the solution for acid by placing in it a piece of blue litmus paper, which will turn red from the acidity of the bath. Four in, drop by drop, a dilute solution of liquor ammonia on the surface of water, stirring the solution while the ammonia may thoroughly mix, until the discoloured litmus paper resumes its blue tinge, but not beyond. The acid neutralized (by the ammonia) the solution still boiling black and muddy, and finally clears as the organic matter is precipitated, sticking to the bottom and sides of the dish, the coagulated albumen rises as a thick metallic scum to the surface, and the heat dried and left clear and dry.

When the solution is cold it must be filtered and acidified as already explained, with nitric acid. It must be borne in mind that the nitric acid must not be added until the solution is perfectly cleared from organic matter by filtering, because acid holds the organic matter in solution, while the alkaline liquids (in this case ammonia) favour precipitation. The addition of acid before filtering would undo a great part of the work of renovation you have been engaged in, by redissolving the organic matter.

When after several treatments of the disordered bath in this manner, if it persists, there remain two other methods—fusion and precipitation, and re-dissolution.

To Fuse the Bath.—Pour the bath into one-fourth its volume of water, and filter out the precipitated iodide; then, placing it in the evaporating dish on the stove, evaporate to dryness without adding ammonia or other neutralizing agent, because upon adding ammonia oxide of silver is thrown down, and if the bath were now evaporated to dryness, this powder, to which the name fulminating silver has been given, would be thrown down. This fulminate is of a most dangerous explosive character, even under water-heated to 212° Fahr. What is more, a touch is sufficient to cause its violent decomposition.

When the solution approaches dryness it becomes violently and, rises in the dish like soapuds, until some of the bubbles burst, allowing the escape of vapour. Scrape the mass down into the middle of the dish, when the salt begins to liquefy again. When melted it remains quiet, without boiling or steaming, at the bottom of the dish. Insert a straw or splinter of wood, and continue the heat until it ignites, which shows that the organic matter is carbonized, and thus rendered perfectly insoluble. When cold the fused mass may be dissolved in pure water by gentle heat. The organic matter is entirely separated, and will be left behind in the filter. It is now ready for use as a new bath.

To Restore by Precipitation.—Dilute and filter out the iodide, and pour the solution into large glass jars, half filling them, and add a little at a time, and continually agitating the solution the while, finely powdered bicarbonatet of soda; this, uniting with the silver with violent effervescence, forms carbonate of silver, which, being insoluble in water, falls to the bottom of the jar. Now fill up the jar with pure water. When settled, pour off the water, fill up, and more. After several of these, thus right to ten times, to thoroughly wash the carbonate of silver; after the last washing drain off the water, and add, very cautiously, nitric acid, which will dissolve the carbonate of silver with effervescence. Leave the least amount of carbonate of silver undissolved, or too much acid will be added, and the work have to be done again, the organic matter in the bath being dissolved if the silver is made acid. The least amount of precipitate of carbonate of silver undissolved leaves the bath neutral. Now filter the muddy solution.

To throw down Silver in a Metallic State.—Place the solution in a clean evaporating dish with pieces of bright clean zinc, when the silver will commence falling down in a metallic state, the zinc dissolving and taking the place of the silver. In five minutes the whole of the silver will be all thrown down. Pick out the undissolved zinc, and scrape it from the silver clinging to it. Now add to the mixture a solution of sulphuri acid one part, water three parts, to dissolve any particles of zinc which may be left in the dish. Allow this to stand until no more bubbles of hydrogen gas are given off. Pour off the acid, and wash the silver in several changes of water until it no longer reddens litmus paper. The silver is now dissolved in nitric acid diluted with two parts of water, evaporated to dryness, and fused.

ON MICRO-PHOTOGRAPHY.

BY DR SCHMANN.*

The microscope has become an indispensable instrument to the student of natural history. The results of microscopic investigation have widely extended our knowledge of natural history, and have brought to light facts connected with the development of the lower animal kingdom of which, before, we had no anticipation. Daily the microscopical journals bring us new discoveries.

The permanence of microscopic preparations is often very limited, and yet it is very desirable that they should be preserved for scientific as well as instructional purposes. Under these circumstances it is a matter of importance to secure trustworthy images of the same; and how we have to obtain these has been put to the test by all. A draughtsman finds pencilling a microscopic object a most tedious labour, and very often the result is, after all, of an ideal nature; moreover, it requires one skilled both as a microscopist and draughtsman to be able to produce such drawings.

Many instruments have been constructed to lighten the laborious task; as, for instance, Wollaston's camera lucida for microscopic drawings. Overhauzen's drawing apparatus with prisms for projecting the picture on paper, &c.; but photography has now held out a helping hand, and already, in the days of Daguerreotype, the camera was employed for making microscopic pictures.

The first presentable pictures were obtained by Donné. After that, Leon Foucault obtained some results, in 1845, which were used as a basis for the copper-plate illustrations in an atlas of flowers.

With the employment of collodion in photography, and the use of albumenized paper, micro-photography made a big stride of progress. By means of negatives, large numbers of copies could be produced, and with the Lichtdruck process of the present, it is possible to publish books illustrated by micro-photographs. Professor Benecke, of Königsburg, who has translated Moitessier's handbook

* Read before the Berlin Society for the Advancement of Photography.
entitled "Photography as the Aid to Microscopic Science," has shown how much may be done with the new art, although, unfortunately, it is not everybody who has such a well-adapted studio and apparatus as the author I have named. Dr. Fritsch's "Diatomaceae" is another work showing the importance of micro-photography.

The difficulty in obtaining micro-photographs, exclusive of the various colours and the uneven thickness of the microscopic preparations, is the focus difference of microscopic lenses. Even when these can be corrected by application of other apparatus, the operation is a tedious and difficult one, and is not a mode of procedure which can be carried on by the ordinary student of the subject.

Benecke himself says: "It would be desirable to have photographically-corrected lenses," and this wish has since been heard from others; so that I am led to bring forward an apparatus which I have employed, and some specimen prints obtained by it. The most important thing about the instrument is the corrected lens, which is screwed on the microscope tube without an eyepiece. The bellows camera is upon a brass tube, fastened to a horse-shoe pedestal, so that it can be readily focussed by a screw arrangement, and it is brought in a vertical position over the microscope tube, an arm upon the camera being drawn over the tube to shut out the light.

The screen for focussing is a glass plate with fine dia- matic markings, and the farther this is from the lens the larger will be the image. In short, the question of lighting is one of great importance, and the use of condensers with direct light, or limelight, is indispensable. Enlargements of twenty-two diameters may be prepared in this way.

In America, Wales has, according to Rutherford, constructed corrected lenses with one-eighth of an inch focus, but the Hebb of the United States has secured a picture of *Pleurisigma Angulatum*; by enlarging to 19,000 times, a sharp image was still obtainable. Corrected lenses are also, to some extent, manufactured in Germany, MM. Siebert and Kraft, of Wetzlar, preparing them from one inch to one-eighth of an inch focus.

**COLOURATION OF STATUARY.**

BY RICHARD H. ROW, O.M., F.R.S.E.*

But though we may thus see that there are good grounds for eschewing any attempt to copy the actual colours at the same time with the solid forms of nature, there may be no reason why we cannot with the same degree of success in sculpture by adopting some modification of ancient practices.

In order to convey properly the sense of expression in the forcible manner, we must define the positions of the eyes, the characteristics of the lips, and the mouldings of the hair—whether that be of the eyelashes, eyebrows, head, or beard—in a more precise and decided manner so that from cast and contour shadows.

Taking up a photograph or engraving of a head, we find the features and expression brought out by simple light and shade. But the shades are divisible into three kinds—1st, the contour shades, or shadowings produced by the surfaces represented being placed at various inclinations to the incident light; 2nd, the cast shadows arising from other parts of the object, as the light is cut off; and 3rd, the colour shades representing the darkening effects of the colours of the surfaces, or their power of absorbing in various degrees the light that actually falls upon them. And, as supplementary to this classification, we must not overlook the important modifying effects of the more or less polished states of the surfaces.

In the simplest while statuary the effect rests wholly upon the contour and shadows, with occasionally (as in the Veiled Vestal) the employment of the contrast of polished and unpolished surfaces. Now, the purpose of my paper is to suggest and enforce that we should superadd the third kind of shading representative of colour, but in as great moderation as may be, and by preference only using shades of grey when the whole surface has to be painted.

When the general surface of the statue, or other piece of sculpture, has not to be painted, and possesses of itself a tint different from grey, we must be guided in the choice of the two extremes of the scale of shades to be used in our dichromatic treatment by the analogy of an engraving printed in brown or other coloured ink upon tinted paper; that is, if shaded tints to be employed should be such that the natural colour of the material will take it readily of them; and it is open, of course, to apply any such dichromatic scale, even when all the surface of the subject is to be painted or enameled.

Restricting ourselves to the use of such a scale of shades, I believe we could attain to much excellence of effect, without in any degree awakening the disagreeable feeling that results from attempts to give life-like colour. A piece of statuary so treated would, in fact, convey all that an engraving could, with the added charms of stereoscopicity, changing points of view, and changing arrangements of the lighting.

And, as connecting the subject with this Society, I may state that a bust so shaded would be a most valuable addition to the studio of the photographer, to assist him in the practice of the art of sculpture. In the case of big palatial figures we must not only have the cast and contour shadows becomingly arranged, but so tempered in severity as to harmonize agreeably with the positive shades. When the cast shadows are too faint, we have the eyes, eyebrows, &c., given as black marks upon a white ground; and when the cast shadows are made too decided, one or both of the eyes may be lost altogether in the darkness secured.

A weak point in ordinary statuary, arising from difficulties in the workmanship alone, is the absence of the eyelashes; we lose the effects both of the positive colour and of the cast shadows. This defect was well known to the ancients, and examples are still extant in which eyelashes of copper are inserted; and, to make our busts completely satisfactory, it would be necessary to follow some such practice. The defect may, however, be in a great measure supplied by a painted shading on the edges of the eyelids; the inner surfaces being at the same time shaded to represent the carmine shading there.

In thus advocating the employment of neutral tints, or simple light and shadow, to reinforce and complete the effect of statuary, I do not wish it to be understood that I am altogether hostile to the greater boldness and freedom advocated by Mr. John Jones. But I think the dichromatic treatment I have proposed might be erected into a distinct and not unimportant branch of sculptorial art. In carrying it out difficulties would no doubt arise, but we may trust to technical skill also arising to overcome these, should encouragement be given. I add only two hints here of a practical character—1st, Keep the polish or lustre of the flesh tints rather under than over that of nature; but the degrees of glossiness of all the surfaces should be studied so as to reproduce with approximately correctness the effects of regular and irregular reflection. 2nd, When the tint chosen for the nude part of the figure is lighter than in reality, let the scale of shades be all correspondingly weakened.

And now a word in conclusion on the general bearing of the subject. When we look at a complicated pattern of interlacing geometrical figures, the eye, as every one knows, can single out some particular figure and regard it separately, and again and again, new figures or parts of the combination may be so selected at will by the eye. Now there is an analogy between this and the contemplation of an unpainted bust: the eye through the fancy may regard it under all the different aspects that it would be possible to evolve by variations in the painting; and it may be brought forward as the chief objection to the painting of
sculpture, that this freedom of the fancy is curtailed, and the contemplation restricted to one phase of expression alone. Without denying some weight to this objection, and granting that some pieces of sculpture would be best left unpainted, it may be replied that the painting gives the artist the power of fixing the best aspect of his subject, or bringing out that expression which he seeks to convey; and in the case of a portrait bust, every one must admit that the advantages are all on the side of the use of shade-painting or enamelling.

ON THE COMPARATIVE SENSITIVENESS OF VARIOUS PHOTOGRAPHIC PROCESSES.

BY LIEUT.-COL. H. STUART WORLEY.*

I HAVE for some considerable time past been testing experimentally the sensitiveness produced by various modifications of the photographic negative processes, both with the bath and with an emulsion. I have frequently noticed during the course of these experiments that my experience has been opposed to that of others who have recorded experiments in some directions to the contrary of the photographic journals. Where the quality of the negative is in no degree sacrificed by increasing the sensitiveness of the materials composing the film, I have always thought that the more sensitiveness we can impart to the film the more advantage and facility do we obtain in our work; and I think that the subject on which I am writing is of such great importance that I must insist on bringing it under the notice of the Photographic Society. We frequently find it recorded in the journals that such and such a process has given such and such results; but there has never been an attempt to produce those results by a standard measure of illumination, and we finally arrived at the "reductio ad absurdum" in connection with the subject when we were greatly told (though I do not think many people remained grave when they realized it) that a transparency could be printed on a certain kind of dry plate by half a second's exposure to the light of a farthing candle! Feeling, then, as I do, the great gain to the photographic world at large that even a slight increase of sensitiveness gives to a negative process, I venture to make the following suggestion to the president and council of the Photographic Society. I think it would be worth the time and assistance of the photographic public if the council would appoint a small standing committee to investigate from time to time the sensitiveness of the various modifications of the photographic negative processes, wet and dry, that may be brought before them— to do which they would have to establish a standard method of illumination, and use certain standard negatives from which to print transparencies. In my own practical use of a standard Argand gas burner, at a certain distance from which a shelf was placed whereby the printing frame containing the negative and plate on which to print the transparency is laid, and the time of exposure can be regulated to a great nicety. I have used in my experimental work during the last three years one standard negative, from which I must have printed some thousand is of transparencies, and I need hardly say that the information I have in that manner acquired has been of great interest and value. In cases where it has been deemed desirable to take a negative, I have endeavoured, by burning a certain amount of magnesium wire, to obtain a standard result; but I find that the printing of transparencies in the way just described gives results much more certain and more reliable.

If this committee were to be appointed, and if good men were to be found who would undertake this somewhat troublesome duty, we should find that many preconceived opinions would be ruthlessly demolished; we should find that there is no inherent virtue in gelatine over collodion for making an emulsion with, and that a properly made collodion-emulsion is every whit as sensitive (owing to the latitude which may be allowed in exposure and development of a collodion dry plate, and which a gelatine plate is not, in reality, more capable of standing) as a gelatine emulsion; we should find that the addition of ten to fifteen grains of nitrate of uranium to the ordinary silver bath gives a considerable additional to the sensitiveness; we should find that under certain circumstances, current work, Mr. Carey Lea has been correct in pointing out the additional sensitiveness imparted to the emulsion by the use of an iodide therein; and we should find that the use of a chloride in the emulsion or in the collodion used with the bath is an element of insensitiveness, though the reverse attribute has been claimed for it by some writers who have followed in the footsteps of Mr. Carey Lea, whose proposal to introduce it into an emulsion for purposes other than to gain increased sensitiveness.

I could give you many other instances and many other results of my own work; but I feel that I should be in that case be anticipating the labours of a committee that I much hope to see established; and I do not wish to prejudice cases that in all probability would be decided against the use of the various photographic processes.

My proposal will be favourably received by the members of the Photographic Society, and that I shall be supported in bringing my suggestion before the president and council.

---

THE PRACTICAL PRINTER IN AMERICA.

XXV.

Mounting the Prints.

Or all subjects of photography, this has received the least attention. The simple process of mounting is a thing of some little mechanical skill, as I think all photographers will agree with me in saying. The making of the starch paste, if that is used, is at first a little troublesome to the beginner, as is also the glue, gum, &c., and then the placing of them on the cards, although a mere mechanical process, should be done well.

In galleries where only two or three hundred of small cards are printed in a day, surely those few, when compared to fifteen or twenty hundred, which is the daily average in some galleries during the winter season, are not a very small fact, and excellent, when we consider that all that is required to make them so is only a little care. What is the effect left upon our minds when we examine prints that are nicely printed, cut, toned, &c., and are mounted badly? Does it not strike us unfavourably? I think it does.

It is acknowledged by many photographers that the starch used in mounting is the cause of their fading; and the reason why this is so universally used is, because all photographers have learned to make it, and because they are either ignorant of its effects on the prints, or, if not ignorant, too careless or heedless to take measures to prevent the use of it. But if this mounting is really the cause of their fading, which I think is partly true (but also I think that too much blame is given to it, when careless manipulation has considerable to do with it), why is it then used? I have mounted prints with starch and one day, after mounting a batch of them with it, I saved a few for myself for the purpose of experimenting, and wrote on the back of the mounts such writing that would tell me at some future time why I had saved these particular prints. I experimented considerably with them, and placed them in a very dry atmosphere for a month, then directly in a very damp cellar for another month, in a dark album for a fortnight, among the samples of work in the reception-room, on a shelf in the chemical-room for a week, in the dark-room for a fortnight, where there was a strong smell of cyanuret of potassium, ether, &c., down cellar again, under strong diffused light for a fortnight, in the damp-box for a week, and in spite of all these tests I could not get the
prints to show either stains, bleaching, cockling, or fading. Very little, if any, of the former were detected, and the prints tested well, and "they stood the test like a matter, and, as far as theory goes, it is correct—that the starch used in mounting the prints would form an insufficient "rubbing down" of the prints after mounting. The small prints, as they are removed from the water, are laid in a neat pile face down. A suitable size frame, say 8 by 10, is covered with the same size piece of clean moistened paper, which is thoroughly wetted, and when the prints in the water are thoroughly rinsed, they are laid in a perfectly even bunch on it, the different sizes to themselves. The paper laid on the glass serves to keep the prints damper than the bare glass would. Use a clean paper every time you prepare to mount the prints. Ths prints are mounted for convenience in a wet state. The object of mounting with the starch or glue, as it is called, is to make the process cheaper, and thus bring the print in perfect contact with the card-mount, which is sided very much in the so-called process of "rubbing down."

You should apply the starch or glue to the prints quite thinly, and after laying them carefully on the mounts, lay a sheet of thick writing-paper—or, better still, some un-inked printing-paper—on it, and rub the prints, commencing at the print in the centre and rubbing outwards, which process will perfectly remove all air-bubbles from under their surface. Then bend backwards the mounted print, and rub the finger along the edges carefully of all the sides of it. I recommend beads in of the back of the mount because, in drying, the print draws the thick cardboard inward, and this counteracts it, and the dried prints will be flat, and can consequently be mounted better. Then, make the gum-water, add it gently, and then they would not be so likely to cockle as they would if they were dried by the fire.

In mounting large prints, lay a print at a time on some thicknesses of clean paper and where there is no trace of starch, and after pasting mount it on a suitable size cardboard, and rub well from the middle outwards as in the small prints, examining afterwards to see that there are any air-bubbles which escape notice, and if so, be sure to remove all of them. When applying paste to the print for the purpose of mounting, examine the surface, and if there are any hard bunches of paste, dirt, &c., even if in a small quantity, as a lump or two, remove them with the finger-nail, as these places will show after they are mounted, and spoil the look of the work. Dry these prints on a suitable size book, except for the purpose, and under a sheet of blotting-paper, and when they have been an hour, remove to another place of the book, under fresh and dry blotting-paper.

Chinese or Indian Ink.—Although the Chinese prepare their ink from the kernel of some angygalaceous fruit, yet, by the aid of our present chemical appliances, we are able to produce a composition in no way inferior to the best Chinese ink, by the adoption of a formule which is given in Riquet's treatise on the "Manufacture of Colours." The following is the formula:—Calcinated lamp black, 10 parts; boghead single black, in impellable powder, 80 parts; indigo carmine, in cakes, 10 parts; carmine lake, 6 parts; gum acacia (first quality), 2 parts; purified ogeal, 20 parts; alcoholic extract of mastic, 6 parts. The gum is dissolved in 50 to 60 parts of pure water, and the solution filtered through a cloth. The indigo, carmine, lake, lampblack, and single black are incorporated with this liquid and the whole ground upon a slab, with a muller, in the same manner as ordinary colours; but in this case the grinding takes much longer. When the paste is thoroughly homogeneous, the ogeal is gradually added, and then the alcoholic extract of mastic. The more the black is ground, the finer it is to be. The black is then heated under an air, until it has acquired sufficient consistency to be moulded into cakes, which in their turn are still further dried in the air, out of the reach of dust. When quite firm, these cakes are compressed in bronze moulds, having appropriate designs engraved upon them. The moulded ink is then wrapped in tissue, with a second envelope of gilt paper. The ink which has been prepared in this manner possesses all the properties of the real Chinese article. Its grain is smooth, it flows very well, mixes perfectly with many other colours, and becomes so firmly fixed to the paper that other colours may be spread over it without washing it out. Scientific American.
that the addition of from ten to fifteen grains of nitrate of uranium to the ordinary silver bath for negatives gives a considerable accession of sensitiveness. Whether this proportion of the uranium salt is intended to be added to each ounce, or to some indefinite number of ounces, was not stated. Captain Abney, who affirms a similar experience as to the gain in sensitiveness, adds, if we may rightly, ten grains of the uranium salt to each ounce of silver solution, and we presume that the addition referred to by Col. Wortley is intended to be in similar proportion. This is a novelty which can be very easily tested by every one, and it is a method which will not involve any manipulative trouble or departure from routine. The precise mode of the acceleration of the action of the solution appears to have been ascertained, but, remembering the known photographic qualities of the nitrate of uranium, it does not appear necessary to go far to find a reason. It may possibly be too much to say that its fluorescent properties have nothing whatever to do in the case; but we do not think there is any ground for supposing that they have. In the first place, the fluorescent qualities would become almost nil—or, at least, inappreciable—in the thin film of the free solution on a drained plate, or the still smaller trace left on a dry plate which had been excited in a bath containing the uranium salt; and in the next place, the known action of the nitrate of uranium is quite compatible with the experience of Captain Abney and Col. Wortley. The test-nail of uranium and some other bodies when exposed to light part with one or a few of their atoms and have a reducing power; some of the interesting processes of Sir John Herschell have been based upon this reaction. If a piece of paper be coated with a solution of nitrate of silver and nitrate of uranium, without any chloride or haloid salt of silver, it will readily darken under the action of light, which with nitrate of silver alone it would not. To this new feature of the operation. Under the action of the light the nitrate of uranium passes with oxygen, and acquires the power of reducing the nitrate of silver in contact with it. It does not seem unfair or unnatural to suppose that the same reactions are in operation in the film of colloid in which nitrate of silver and nitrate of uranium are in contact, plus the haloid salts, on which the silver salts chiefly depend. Whatever may be the theoretical explanation, it is certain that there is one which is so easily tested that no one need remain in doubt who is interested in securing the advantages it offers.

Some months ago we published details of Dr. Van Monckhoven’s proposal to reduce exposure by the use of a more energetic developer. An experimental committee of the Photographic Section of the American Institute was recently appointed to try the matter, and they report that they find that the exposure is reduced one-third by the use of this developer, twenty seconds giving the same result with this developer which could only be exposed by the ordinary developer with an exposure of thirty seconds. They also found that a similar reduction in the time of exposure might be secured by the use of a developer containing sulphate of magnesia as well as sulphate of iron. Here is the formula:

<table>
<thead>
<tr>
<th>Substance</th>
<th>Quantity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Water</td>
<td>16 ounces</td>
</tr>
<tr>
<td>Sulphate of magnesia</td>
<td>2 ounces</td>
</tr>
<tr>
<td>Protosulphate of iron</td>
<td>1 ounce</td>
</tr>
<tr>
<td>Acetic acid No. 8</td>
<td>3 ounces</td>
</tr>
</tbody>
</table>

The ordinary developer used by the committee was composed of—

<table>
<thead>
<tr>
<th>Substance</th>
<th>Quantity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Water</td>
<td>16 ounces</td>
</tr>
<tr>
<td>Protosulphate of iron</td>
<td>1 ounce</td>
</tr>
<tr>
<td>Acetic acid No. 8</td>
<td>2 ounces</td>
</tr>
</tbody>
</table>

The advantages offered by the modified developer are as easily tested as those offered by the addition of uranium to the bath. We shall hope to hear reports of the experience of some of our experimental readers on both methods.
OBITUARY.—MR. CHARLES BREESE.

We announce with much regret the death of Mr. Charles Breese, formerly of Birmingham. Most photographers are familiar with his name, and with the charming and poetic transparencies for the stereoscope which he made his special work. Mr. Breese, a gentleman of a singularly ingenuous and inventive turn of mind, as illustrated in many branches of Birmingham industry, early made instantaneous photography a special study, and his work in this direction many years ago attracted the attention of royalty. Being but ill satisfied with the imperfect rendering which a paper print yielded of some scenes in nature's poetry, of which the negative contained a fairly complete register, he confined himself chiefly to the production of transparencies for the stereoscope of scenes instantaneously produced, often of a daring nature: a breaking wave, a storm at sea, a balloon in the air, a sparkling waterfall, the rising or setting sun seen through rifts of driving clouds, moonlight scenes, groups of art objects consisting of all polished silver and glass, and a variety of other subjects in which any special and unusual charm could be secured. If it presented unusual difficulties, the charm to him became greater, and he rarely failed in securing success. His mode of printing his transparencies, generally on wet collodion, and frequently from two or three negatives, was retained a secret, and the mode by which many of his results were obtained was the subject of much speculation and curiosity, which he left unsatisfied, feeling, doubtless, that the mystery of the art lay at the heart of the art. Some years ago he devoted himself to the commercial production of his transparencies, for which he had found, as an amateur, a considerable demand. He has practically had no rivals in his special work, for whilst many have produced fine instantaneous pictures and good transparencies, Mr. Breese's work could always be distinguished in a moment by its rare delicacy and beauty in production, and the feeling of poetic and artistic values which pervaded his pictures. He had been for some years in a state of declining health, and was, we understand, staying at Matlock in search of the conditions required by an invalid, where he died on Monday morning last.

THE VIENNA VOIGHTLANDER MEDALS.

It may interest our readers to know the nature of the medals offered by the Vienna Photographic Society during the course of the present and forthcoming years. Candidates for membership by becoming members of the Society, and all communications are to be addressed to the President, Dr. E. Hornig, 3 Haupstrasse No. 9, Vienna. The names of those competing must not be openly stated, but should be contained in a sealed envelope having a motto or device on the outside corresponding with one on the packet with the communication, negative, pictures, &c.

A gold medal of the value of one hundred and forty ducats, or one costing forty ducats together with one hundred ducats in money, for a process to increase the sensitiveness of wet negative plates. The increase of sensitiveness shall be so great as to make it possible to give only a quarter of the exposure of that usually allowed to produce a detailed picture. The increased sensitiveness shall not be obtained at the cost of vigour or harmony of the picture. This process, again, shall be such that half an hour's exposure can be given, say, in the case of an interior, and that it can be employed anywhere without difficulty. Processes which give good results without actually fulfilling the requirements will be rewarded with prizes of lesser value. Competitors must forward their communications by the 31st October, 1875.

A modified photo-relief printing process.

A method of producing photo-mechanical printing plates has recently been patented in America by Mr. L. E. Levy and D. Bachrach, the results of which are highly spoken of by the editor of Anthony's Bulletin. It will be seen that a gelatine image in relief is obtained in the usual manner, the modifications being chiefly in subsequent details. The gelatine relief is plunged into a solution of nitrate of silver, and, subsequently, into sulphate of iron, for the double purpose of obtaining crispness and sharpness in the gelatine image, and of rendering its surface conducting in the electrolyte bath. The precise mode of printing finally employed is not stated. The following is the specification:

First. Gelatine is dissolved in water to the consistence of a thick jelly, solid at ordinary temperatures. When required for use the solution is liquefied by heat. To this solution is added a saturated solution of bichromate of potassium or ammonium, or its equivalent in rendering the organic substance of the film sensitive to light, in quantity sufficient with the temperature and with the class of work required to be produced.

Second. This mixed solution is now spread upon glass plates which have been thoroughly cleaned, and poured on until a thick layer covers the glass evenly over the whole surface. The thickness of the layer depends upon the general character of the work for which it is intended; the greater the relief required the thicker should be the film. It should, however, even for the most uniform work, be of considerable thickness. The plate is allowed to dry either spontaneously, by ordinary evaporation, or by being placed in an oven and heated moderately until hard.

Third. This film is now exposed under a negative of adequate density, such as are generally used in printing copies of line-engravings, to solar light. Care must be taken to have the rays of light reach the negative directly from the perpendicular. To end side light must be excluded, so as to prevent the film from being affected by diagonal rays. The amount of exposure to light is an important element in this process. This exposure can scarcely be too prolonged; it should be at least half an hour to direct sunlight. Portions intended to remain white may be protected by an opaque covering or coating on the negative. Two, three, and even five hours' exposure to diffused light (reaching the negative through a long box) is now complete the requisite action. This is to ensure the complete reduction of the bichromate to chromic acid, thus securing the most perfect insolvability of the exposed portions of the sensitive film, even in the finer details of the picture, and thus to keep all the lines on one plane.

Fourth. After the exposure of the film, the edges of the plate are provided with a rim of melted wax, which is to prevent the film from peeling from the glass by the continuance of any accidental peeling at the edges.

Fifth. To partially swell the film it is now soaked in cold water, but only during a limited space of time, dependent upon the thickness of the film and the quantity of bichromate used in sensitizing it, with the view of retaining a quantity of the bichromate as a base for the next subsequent operation.

Sixth. The film—still retaining the varnish—of the bichromate is then taken out and plunged into a solution of nitrate of silver. Here the swelling is completed, which condition is negatives of 10 by 12 measurement at least, one being a landscape, one an interior, and one a landscape with architecture, together with every one of each, and twelve prepared plates; details of the process, as also of the chemicals used, must be given. The candidates must forward the same by 1st March, 1876.

Three silver medals will be given for: —1. A collection of twelve nature studies, taken with an aid to aid artists. 2. A collection of twelve instantaneous stereoscopic pictures. 3. For a collection of transparencies for the stereoscope. Negatives and two copies to be sent of each subject, not later than the end of October, 1876.
indicated by the chromic acid in the affected portions showing marked signs of red-tinting. The silver solution, while-in, and in this case the shrinking of the same, and the resulting bi-chromate of silver offers the requisite basis for the subsequent operations.

Seventh. It is now washed under a tap, and immediately plunged into a solution of the sulphate of iron in water. This solution is calculated, to enable the reduction of the metallic deposit to proceed more freely. The action of the iron solution is allowed to continue until the picture is plainly visible from the back of the glass on the upper black ground. A metallic substance is thus obtained which is hung down through the entire thickness of the film, instead of being on its more superficial deposit. This is an essential element to the success of the work, and must be fully carried out. It has another important effect upon the film, inasmuch as it coagulates or "sets" it, rendering it capable of enduring without alteration through the subsequent operations.

Eighth. When taken from the iron solution the plate is coarsely washed under a tap, and immediately flowed with a dilute solution of the sulphate of potassium. This application turns the film to a black colour, consequent upon the reduction to the sulphate of silver, and the action of the solution is continued until the entire deposit of metallic silver is uniformly reduced to a sulphate.

Ninth. In this condition the film is sufficiently electrolytic for all practical purposes. It may now be hung in the electrolytus, with the silver deposit on the negative of the emulsion thus secured.

Tenth. To insure the easy and rapid action of the battery we cover the sulphurated film, after drying, with a coating of platinum. The dried sulphurated film receives the platinum with the greatest facility, and it may be brushed on and fixed as easily on wax.

Eleventh. The plate is now attached to a wire or other suitable arrangement by which it may be connected in the precipitating trough with the positive pole of the battery. Here it receives the deposit, which may be completed with much less rapidity, according to the condition of the bath, battery, &c.

Twelfth. In certain conditions of the copper solution the copper shell does not readily leave the film, but tends to adhere to it with sufficient tenacity to endanger the shell in being taken off. To preclude breaking it in stripping from the mould, the glass plate is evenly heated to a moderate temperature, in which condition the copper plate may easily be lifted off the glass, carrying the film of gelatine with it. It is then plunged into a solution of concentrated lye, which readily dissolves the gelatine, and leaves the face of the electrolyte bare and clean.

This is the complete process. We append the following references to details and modifications:

First. Ordinary glue may be used in place of gelatine, being preferable to many kinds of woods.

Second. The swelling may be brought about in a solution of alum, in a solution of the persulphate of iron, in a solution of tannic acid, and in other solutions and liquids, and the silver deposit be afterwards precipitated.

Having described our invention, we claim the following:

1. In the preparation of photo-relief plates for printing, &c., the described process of effecting the complete swelling of the gelatine film as a continuous operation, after being partially swollen in water, by treatment with the nitrate of silver solution, substantially in the manner and for the purpose set forth.

2. The described process of producing the deposit of metallic silver on the surface and the body of the gelatine film, in the manner and for the purpose substantially as set forth.

3. The described method of producing an electrolytic deposit of sulphate of silver by means of sulphate of potassium, substantially in the manner and for the purpose set forth.

4. The described process of producing relief-plates for printing and other purposes, consisting essentially of the several steps above described in their order of succession, substantially as set forth.

**VISCUOUS AND COLLOIDAL SUBSTANCES IN THE DEVELOPER.**

**BY D. WINTHASTLEY, F.R.A.S.**

It is known that when viscous and colloidal bodies are added to developers, a retardation of development ensues, and the substances in question may be looked upon as true restrainers. On the fourth of August last, Mr. giving some attention to this matter, I re-performed experiments illustrative of the point.

Collodion plates were washed, and their halves exposed for equal lengths of time in immediate succession, the same instruments and objects in each instance being used. The halves were then developed simultaneously with iron solutions having equal strength; one half being brought out with plain iron alone, the other with iron which was saccharated. The following tabular arrangement of only three experiments will show the result at a glance the action of the sugar and its influence to restrain:

<table>
<thead>
<tr>
<th>Experiment 1</th>
<th>Experiment 2</th>
<th>Experiment 3</th>
</tr>
</thead>
<tbody>
<tr>
<td>Thick end of 6&quot; film—1st half of plate.</td>
<td>Thick end of 6&quot; film—1st half of plate.</td>
<td>Thick end of 6&quot; film—1st half of plate.</td>
</tr>
<tr>
<td>Developed with solution containing in one ounce—iron ammonium sulphate, &amp; 1 dram; water, quantum suff.</td>
<td>Developed with solution containing in one ounce—iron ammonium sulphate, &amp; 1 dram; water, quantum suff.</td>
<td>Developed with solution containing in one ounce—iron ammonium sulphate, &amp; 1 dram; water, quantum suff.</td>
</tr>
<tr>
<td>Result—slightly more detail and slightly more density than the 2nd half.</td>
<td>Result—slightly more detail and slightly more density than the 2nd half.</td>
<td>Result—a little more detail, and less the same density than the 2nd half.</td>
</tr>
</tbody>
</table>

In the instances of two of the experiments recorded in the table, it will be seen that those halves of plates brought out with un-saccharated iron possessed somewhat more of density and detail than their neighbours, a circumstance, however, which must be attributed, as I have elsewhere shown, to their being on the thick end of the film.

I am unable with certainty to name the date at which saccharine and colloidal bodies were introduced in virtue of their restraining powers as ingredients in developers, but I find attention called to them by Mr. Wharton Simpson in 1869.

Concerning the mode of action which such bodies take, two statements are all that I have found: the one, that they mechanically impede precipitation, and hence retard development; and the other, that they "cement together, as it were, the film and silver particles thereon."†

The former of these ideas suggests itself as a rational hypothesis, but the latter, it is manifest, cannot be entertained.

If we allow a stone to sink or a bubble to ascend in a vessel filled with water, a certain time elapses before the journey is performed. If treacle be the medium used, that length of time will be increased; or if Canada balsam be employed, the time will be still more prolonged; indeed before a bubble will get clear. And this, as I understand, illustrates the method of retardation supposed to be exercised when viscous and colloidal bodies are made use of in developers. To ascertain, however, for a certainty, if the explanation given be correct, it is desirable by some means to estimate the extent of viscosity produced by the addition of various substances to the developer, for if the theory given be correct, the extent of retardation will be the same where equal degrees of viscosity have been obtained, no matter what organic bodies have been used. For the purpose, then, of measuring in some sort the "thickness" of various viscous fluids, | † British Journal, 1874, p. 306. | Mr. Dunmore in The British Journal, 1876, p. 621. |
I used a Schuster's alkaliometer—an instrument of the kind depicted here below. By fusion, and by filing, I caused the opening in its nozzle to assume exactly such a size that the contents of the vessel when filled with water were capable of being discharged in a minimum time of sixty seconds. The vessel, in the case of each experiment, was filled to the lower portion of the neck (marked A), and when its contents were poured out, it was tilted to such an angle that the level of the fluid reached the portion opposite (marked B), the inclination being gradually increased to keep it there until the amount of fluid left was insufficient to reach that point, when this final inclination was preserved until the last drops were discharged. Repeated trials showed that when the vessel had been filled with water, the noted variation of the period of discharge was but one second out of sixty, and consequent experimental error under two per cent. Various developers were then prepared with different organic ingredients, and varying in viscosity from one degree (one minute in discharge) to four (four minutes in discharge). Their results were then compared, when it was found that the retardation did not depend upon the thickness of the fluid. Assuming no chemical action to have taken place (a point not easy to determine), it is clear that the mechanical action of viscous bodies in developers must be sought elsewhere.

It is known that the precipitated metal forming the photographic image penetrates the pores and external cavities in the body of the film, a circumstance which proves the developer to have preceded it in getting there; and I infer the probability of the film acting as a septum through which the saline ingredients of the developer have to dialyse before reduction can take place effectively. And this necessitation of dialysis I apprehend to be the way in which viscous substances retard the process of development.

HYALOGRAPHY AND ITS APPLICATION TO PHOTOGRAPHY.—LIGHT A MECHANICAL FORCE.

BY THOMAS SIMS.

APRON of this subject, a paper was published in the Journal of the Photographic Society, written by me about the year, I think, of 1859—60. (I have no means at hand of verifying the date). It is one of a series of some thousands of experiments of kindred nature which formed a mode of recreation at spare hours for some years. The substance of that communication, as far as I can remember, was the following.

A collodion positive on glass, made with a collodion the pyroxylne of which was of a powdery nature, or else the collodion of ordinary kind disintegrated by having alcohol of ordinary proof strength, and therefore having enough water to produce the effect. The exposure in complete darkness rather under than over timed; well developed with ordinary proto-sulphate or proto-nitrate developer; fixed with hypo-sulphite; and well washed, and dried.

After this, these photographs were put into sheet-iron boxes in a furnace, the fuel of which was either charcoal or coke; here they roasted at a dull red heat for from a quarter to half an hour, during which time the collodion became calcined, and the silver partly reduced to the metallic state, and partly absorbed by the surface of the glass, the guide being the amber-like tinct seen at the back of the plate when looked at in the light, glass being more sensitive to the sulphide of silver stain than any other with which I am acquainted. The image becomes indelibly absorbed, by continuing the heat long enough, in the most delicate and beautiful perfection.

The pictures are then exposed to the vapour of hydrofluoric acid, a gentle heat being applied to the bottom of lead pan to drive off the vapour with sufficient energy, and the glass kept warm to prevent condensation of watery particles. After a short exposure to the action of the vapour, the plate is washed in warm water, and dried, when the result will be felt rather than seen, for very little can be seen by transmitted light if the glass is fit for the purpose of etching deeply.

Good plate glass is best. The natural surface yields a more visible image merely on the surface, but where etchings on glass are wanted to be looked at merely, finely ground glass is best, for where the silver image does not protect the glass the image will be more transparent, and therefore look dark by transmitted light after being etched.

If any one would wish to stain glass with all the delicate half tones and tracing of the photograph, the above plan is very easy and sure, only the picture must be made from the negative, i.e., a transparent positive. If fixed with cyanide of potassa should be sulphurised afterwards, and washed. The result, after from a half hour to an hour or more in the furnace, will be the yellowish-brown sulphide of silver stain in the body of glass, everything being so smooth and delicate as, or much more so than, the original photograph.

In any way I could ascertain the extent and quality of such engravings was the following simple method. I put a thick slab of plate-glass on the table (a polished lithographic stone answers as well); a single drop of water is let fall upon it in the middle of slab; the engraved glass is put, back downwards, on the drop of water (this is to ensure adhesion, after which no ordinary pressure will break it); a piece of tissue-paper, which has been singed, carefully and uniformly laid down and cut (for transferring drawings), is laid, loaded side up, upon the engraved, and a piece of thin albumenized paper or ordinary writing paper which has no wire-mark is laid upon the loaded paper, and held firmly by the left hand, whilst the right uses a boxwood or ivory paperknife as a scraper. Very pretty blacklead drawings may be obtained in this way.

I am sorry I have not time to condense this communication, and yet say what I mean. My manuscripts have been laid aside many years, and I cannot now refer to them, but the date of the original communication may have been as early as 1854.6.

A few words on Mr. Bovey's ideas under heading—Light a Mechanical Force. All forces become mechanical if applied. Whenever we by the laws called chemical disturb the affinities of material elements, we at some time unbend or retie the most titanic force or forces. Whenever there is chemical action taking place, then one of the phases of force shows abnormal conditions. Every ingenious invention which goes to prove this is useful, because it popularises science by giving ocular demonstration; but those who can deduce from the facts of general science, and such publications as Professor Crowe's "The Correlation of Forces," Tyndal on "Heat and Light," Rev. M. Bircks on "Matter and Ether," etc., are as sure that light is a force as that heat is a force, or that electricity is a force; mechanical if mechanically applied, as though they could, like Thirriol, ride on a sunbeam.
HOW TO MAKE A BELLOWS FOR A CAMERA.

BY R. L. F.

First measure the inside of the camera, which is, let us say, a half-plate size, which we will say is 7 inches by 6 inches inside. Make a block or mould of boards nailed together a little smaller than the inside of camera—say about 3 inches smaller. A little longer than the bellows is required—say 15 inches. Get a piece of good black twill about 13 inches wide and long enough to go right round the outside of mould and lap over 3 inches. Paste the edges together, making a firm joining, taking care not to paste the mould. Over the whole of the twill paste a piece of orange-coloured paper free from holes. Then cut some pieces of cardboard to form the folds,—say 72 pieces, 36 of which will have to be 6½ inches long, and 36 5½ inches long, and each ½ of an inch wide, with each end bevelled to form the corners. Commence about an inch from one end, and paste the pieces of cardboard on all round with the long and short bevils opposite each other, thus:

leaving a small space between each for folding. The long and short ends should come opposite each other at the sides when all are put on, which will be 18 on each side. Paste over the whole another thickness of orange paper, and over that again another thickness of black twill, last side outwards, making the lap where the bottom of the bellows is intended to be. Thin leather can be used instead of the outside twill, but I find twill answer admirably; one made with that material, for a 12 by 10 camera, I have had in constant use about twelve years.

It should now be left till quite dry, then taken off the mould and gently folded. About an inch is left at each end without cardboard for tacking inside the camera, which should be done with strips of leather or thin wood over it, so that it may hold it in the camera firm and strong. The bellows will be about 1½ inches thick, and will allow focussing from about 4 inches to 14 inches. I find good four paste, made rather thick, and with a little powdered alum in it, much better than glue.

If this description is not clear enough, I shall be pleased to give any further information I can.

NEGATIVE RETOUCHING VARNISH.

BY JEAN EPPLE.

There are many kinds of retouching varnish used by photographers, some purchased commercially, some made up at home; but I must frankly admit that none of those I have tried have given me satisfactory results. Moreover, the mixtures that one boys are generally of an expensive nature.

For some time past I have prepared and employed with much satisfaction a formula for a negative retouching varnish which I can strongly recommend, and which is largely employed in Vienna, and has been for some time. It consists of a solution of American colophonium or resin in rectified oil of turpentine, so as to secure a liquid of the consistence of a transparent colloidon. The proportions generally are:

- Oil of turpentine ... ... ... 2 parts
- Resin ... ... ... ... ... 1 part

but they vary according to the nature of the constituents.

The powdered resin is added by degrees, and it is allowed to dissolve by being placed in a warm locality (in the sun in summer), the mixture being shaken up continually. By adding more and more resin the right consistence is soon attained, and a little experience teaches what should be the proper thickness; the resin should dissolve entirely without leaving any residue behind.

To apply the varnish a small quantity (about two drops for a carte-de-visite) is put upon the negative and rubbed over by means of a soft rag which is stretched over the finger, the rubbing being done smoothly. If the varnish sticks much to the film during the rubbing, the solution is then too thick, and must be diluted with a little oil of turpentine.

The varnish is allowed to dry upon the plate for a few minutes, and then it is possible to retouch the surface with any pencil, no matter how soft or hard, as well as upon paper. I generally employ Hardmann’s Nos. 3 and 4, which generally answer for most purposes. In order to put in high lights in the flat portions of drapery, &c., I seldom employ colour, but make use of No. 2 pencil, by means of which the most effective high-lights may be secured, such, for instance, as are seen upon lace, &c. As a rule I render all high-lights with No. 2 pencil, and retouch face and hands with No. 3; while to make any portion more harmonious and to give the appearance of uniform grain I employ No. 4. Translucent spots in the negative I prefer to cover up with white, which seems to me to answer the purpose better than carmine.

In order to remove any retouching from a negative which does not appear sufficiently good, I take pure oil of turpentine, and rub over the surface with a soft linen rag just as I described above when applying the varnish. The varnish may also be used with safety for the manipulation of very old plates, as by its employment no fear need be entertained of the film breaking or springing, as is often the case when old films of varnish come to be worked upon by a sharply pointed pencil.

Correspondence.

DEVONSHIRE SCENERY.

Sir,—There is one spot I ought to mention before passing on to Clovelly, that is well worth at least three or four negatives: I refer to Kenwith Castle, in Abbotsham, and now occupied by the worthy rector of that parish. This place is about two miles from Westward-Hill, and has a name, a character, and a history; or, rather, that line between myth and history. It was occupied by Odun, the brave Earl of Devonshire, who fought Hubbs, the Dane, and defeated him under the castle walls, and drove him into the sea. Our postman poet, Casper, has embodied this page with a living reality:

"The Danes were below the castle wall
When Hubbs spoke to his band—
'Tis tower so strong, my true men all,
No Northernan shall withstand.'

Spake Odun, the Earl of Devonshire,—
"Thy Northernan may be true,
But before brave Odun yields his sword,
They have much rough work to do."

Though this place is much modernised, yet the grounds around it, rising in artificial mounds, indicate that the place was used for defensive purposes.

Portledge, Peppercombe, and Bucks will well repay some hours to each place. The points are easily reached from the main road to Clovelly. The two former have never been done; each has some fine bits of rocky scenery. The first named place is remarkable for the termination of the red sand bed that runs in a narrow strip through the whole of the North of Devon. Peppercombe has a place known as the “Castle,” but why it is called by that name I am unable to say; but that object, with the limekilns and rocks in the foreground, make a good picture. The morning, in fact the early morning, will be the proper time to take each of those places. These spots
lying rather out of the beaten track of tourists, have not been kept hidden from the sight of the photographer. It can, however, be beautiful, as a rule, will not sell," consequently will not pay for doing. "Bucks Mills," lying within sight of Clovelly, has only been photographed by one professional photographer, and only with partial success, the points from the house not being visible. The town and its pictures, as a commercial speculation, would sell with the other local views, because there is a peculiarity and quaintness about the place that is equal to Clovelly, and it is all its own.

Two miles further on we come to the "Hobby Drive" of Clovelly. "Hobby Drive" is the "Hobby Drive," and certainly it is one of the most charming that can well be imagined. For two miles we pass under a canopy of thickly netted trees, through which, and under the "Quarter Deck" is reached a pace is invariably made, feeling as if we were going to the Channel, and known as Hartland Point. Clovelly lies lowly on the greatest bend of the bay, flashing back the rays of the morning sun from its white cottages and the dense masses of foliage, while shooting out from its little semi-circular pier are the calm and bold rise of Sandy Island, its white lighthouse glittering as a pillar of salt, and the grey granite peaks of Rat Island wonderfully distinct. This clearness of Sandy is known to fishermen as a sure sign of rain. This is the picture from the Hobby Drive—this the fascination of the photographic art. Now we see the clearness of the air, over which they have command, is the use of short-focus wide-angle lenses which dwarf the distance. I fell into this error myself; but I saw a picture the other day in which this was avoided, and there would have been but little to be desired for the sea being almost a patch of white. The morning is the best time for taking this view. Pass on towards the village, and see four or five negatives would well repay the trouble of securing. Having reached it, the first business after supplying the warm robes for the man at the "New Inn," there being another hostelry there, will be to walk down the steep and slippery street to the little pebbles built pier, and take a look at the tiers of cottages that rise above. One is at once struck with their picturesque character and peculiar quaintness, and how any one, whether he be fisherman or not, could be drawn at some remote period to fix his dwelling on the very edge of the rock against which the sea was ever beating. It will be seen that all the views from the pier and beach will be better taken early in the morning. The special views I will mention, yet the interest attached to them. I remain, sir, yours respectfully.

THOS. TRIMBLE.
Bideford, May 18th.

WHAT TO DO WITH RESIDUES.

DEAR SIR,—As an amateur photographer with a fair knowledge of practical chemistry, I was very much pleased with your article last week and it so accords with my own experience, that I quite agree with you that it is high time the grievance should be remedied.

Only last week a photographer told me that he sent seventeen ounces of residues to a refiner, who sent him back two and a-half ounces more, and that was being made 1.5% less than silver, although, taking his account of the character of the "waste," I feel confident that it contained at least six to eight ounces of the metal itself. This matter in my opinion is one capable of an easy and effective remedy; but the first step is, that photographers should be able to judge for themselves, within moderate limits, the approximate value before sending it to the refiner. This can be learnt literally without any chemical knowledge, and I propose (if you approve) in two or three very short articles to give a few data by which they may be able to protect themselves.

I may say that my object in doing this is simply from the fact that as an amateur I owe a great deal to the profession. I have been so fortunate, rather to my surprise, that photographers and refiners are not inferior than most men, and in trying to obtain the practical knowledge I required, I have found them always ready, not only to impart the information I have asked, but to put me up to the little "wrenches" and "dodges" which are of such great practical value. If I can in a single degree repay the obligation it will give me much pleasure. I am, dear sir, yours, &c.

PHOTO CHEMICO.

[We shall have much pleasure in receiving the further communication of our correspondent. — ]

FLEXIBLE NEGATIVES.

DEAR SIR,—In your leader of yesterday I find a suggestion that had also occurred to me—to use sensitised bands.

Further on the effect of texture is deplored. I have had a "happy thought." When in the East, I often admired the Chinese and Japanese translucent "rice paper," which I think is just what we want to produce a flexible negative. It presents an appearance similar to that of a very thin sheet of white wax, such as is used for artificial flower making, but is much stiffer, and although it would not bear double up, it might be rolled. Further, there would be no difficulty in obtaining the article in quantity at a very moderate price.

I had not, at the time I refer to, been bitten by photography, or should probably have tried the question on the spot. I have none of the paper by me, but if any of your readers should have specimens of this Chinese paper or rice paper, I shall be most grateful to receive them on this paper, and be willing to sacrifice a curio to the art, I hope they will acquaint me with the result.

In the mean time I shall endeavour to hunt up a sheet or two and try for myself. I scarcely doubt success, and will certainly communicate the result through your columns. I am, dear sir, yours truly,

L. T. ROLLS.
Alme Cottage, Lymington, Devon, May 13th.

Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The ordinary monthly meeting of this Society took place on Friday, May 14th, in the rooms of the Society of Arts, the Rev. F. F. STATTHAM, M.A., F.G.S., president, in the chair.

The minutes of the former meetings having been read and confirmed.

Mr. J. B. SAWYER gave some interesting details of the gradual progress of carbon printing from its origin, and very clearly stating the improvements made by each inventor and discoverer who had given attention to the process, from Mungo Ponton, Becquerel, Poitrenin, Blair, Abbe Laborde, Swan, Johnson, to the latest improvements in double transfer invented by himself, consisting of a moist sheet suspended to the carbon tissue, which, when dry, allowed the picture to be peeled off. A practical demonstration of the process by Mr. Sawyer was then given.

The President, in passing a vote of thanks, said he was most particularly pleased with the history of carbon printing which Mr. Sawyer had so graphically described, and asked whether the process was applicable to large works, such as copies of oil paintings, &c.

Mr. Sawyer said that for very large prints there was no other way. Mr. A and the flexible strip which was being made works 40½ by 9½in. Replying to a question by a member, Mr. Sawyer then made some practical remarks respecting the printing in conjunction with the use of the actinometer, and threw out a hope that some day it might be possible to see the printing.

An interesting conversation ensued, during which it was stated that any amount of brilliancy could be given to a carbon print by hot rolling.

Mr. Wilkinson then read a paper entitled "Archer's Formula," and then put a question to the members, enquiring why chlorate of silver (as mentioned by Archer for the exciting bath) was not experimented with now?

Another interesting and practical conversation then took place. The Chairman said it was often useful to look back to old formulae, and thought, by careful reading of old original ideas, a large amount of information might be gained.

After a vote of thanks the meeting was adjourned.
C. T. ROLLS.—Boric acid was doubletless meant. We have not
tried it; but we think you are in error in supposing that boric
acid would precipitate the silver, unless, indeed, the silver solution
we e alkaline.
A. M. S.—Many thanks. You will see, however, that the informa-
tion we have given is in your last.
A. H. ASHLEY RANKS.—Many thanks for your courteous informa-
tion, which is, however, very sad.
J. BURG.—Thanks for further hints. We shall again call attention
to the matter of air.
C. M. SCHRIEBER.—If we heard of anything likely to be of use to
you, we will write.
CAPTAIN T. T. G. W. A. C. A. wishes to thank those of our corre-
pondents who have given him information in relation to the scenery of pho-
tographic interest in Devonshire.
D. DE LAUDE.—Thanks. The matter shall receive attention in
due time.
J. MCC. —The advertisement, so far as we know, is bona fide,
but inquiries will be made as to correctness of address.
Several correspondents in our next.

Note.—During the month, as will be seen from the foregoing table, we have had many fair weather days, out of 23, the 16th being the brightest, and
generally the light has been very active. It will be remembered that April, 1873, was very warm, considerably warmer than April, 1872, as will be seen by comparing my tables in your impression of day 8th, 1874, with the present. The rain during the month amounted to 11 inches, and
was very much below the average for the month, 27.4 inches, of 11 inches in height, which generally visit here very early was on the 18th, and the first rain was on the 26th.

The weather up to to-day is fine, but hazy. Rain is much wanted to promote vegetation.
PHOTOGRAPHY IN AND OUT OF THE STUDIO.

Gin's Baby—Salicylic Acid—The Vienna Exhibition—

Lord Lindsay.

Gin's Baby.—Few photographs have acquired such fame as Mr. Rejlander's "Gin's Baby," which is to be seen in the windows of every photographic dealer, and which is one of the few, the very few, studies produced by that master photographer, of a profitable nature. Mr. Draper, an old friend of Mr. Rejlander, and well known as one of the founders of the Savage Club, in writing about copyright the other day in the Pictorial World, tells us of one thing about this popular little picture. Mr. Rejlander one day had an infant for a sitter, and before he could obtain a presentable likeness, suddenly caught the child in a fit of passion. The image thus produced, he enlarged, touched with chalk, and again reproduced. After he had taken all this trouble to secure a good artistic picture, somebody came forward alleging that he was the grandfather of the original subject, and claimed, not only copyright, but actually an account and payment of all profits made by the sale. Nay, more, he even issued a writ to enforce his claim, although he did not, fortunately for Mr. Rejlander, continue the proceedings. Thus the proceeds of this picture, which was, perhaps, the only one that ever brought its producer a slice of luck, was well-nigh lost in law expenses. We believe that seven or eight thousand of this little picture were disposed of, and although but a tithe of the profits only reverted to the photographer himself, these amounted to a substantial sum. When first sent in for exhibition at Pall Mall East, the picture was called "Mental Distress," or something of the kind, but the Secretary, in cataloguing, rechristened it, and gave it to the public in the guise of Mr. Jenkin's popular little book. The change did not, however, please the artist, and he demanded that the original title might be substituted in the next edition of the catalogue; but his request was of little avail, for despite all he could say, "Gin's Baby" was in everybody's mouth, and it was already beyond the power of any one to change the name.

Salicylic Acid.—Salicylic acid, the use of which has been recently suggested in photography, is a good preserving medium for many things, and will doubt be found useful as a means of preventing the decomposition of some of the liquids and solutions used by photographers. Further experiments are necessary to determine the influence of this body upon the chemicals and compounds employed in photography, but it may no doubt be used in most cases in lieu of carbolic acid. It is difficult to dissolve in cold water, but is readily soluble in hot water, as also in both alcohol and ether. It has far more antiseptic action than carbolic acid, and has neither the disagreeable taste nor smell of the latter. It lends itself, therefore, readily to medicinal purposes, and would be exceedingly useful for preserving eggs, fruits, and vegetable matter of various kinds, such as are prone to become mildewed or rancid. Salicylic acid has been known for some time past by chemists, but it is only lately that Dr. Kolbe, of Leiпис, has shown how it can be made artificially in large quantities and at a moderate cost. We should think that in most cases it might be employed for preserving solutions of gelatine, albumen, starch, &c., sweet and good; but we repeat, photographers will have to study its action more closely before it can be universally employed in medicinal purposes.

The Vienna Exhibition.—The opening of the Austrian Photographic Exhibition has taken place at Vienna, and we have news that the collection is considered a satisfactory one. The exhibition is held in the Imperial Museum for Science and Industry, and the pictures, to a large extent of a high character, make a most favourable impression upon the visitor, the lighting, with one or two exceptions, being very satisfactory. The best pictures in the exhibition, according to the Photographische Notizen, are some magnificent prints of large size taken by the Court Photographer, Victor Angerer; Fritz Luckhardt's stereoscopic studies, which it will be remembered attracted much attention in our own exhibition two years ago at Pall Mall East; some portraits, large size, of Vienna celebrities taken by J. Gertinger; some excellent transparencies of microscopic subjects prepared by Caarl Haack, of a class therefore, such as have as yet been little included in exhibitions in this country; studies of animals by L. Scholdisch; interiors by Rückwardt of Berlin, Lichtdruck prints by Hoffmeier and Jonas of Dresden, phototypes of L. C. Zamaraki of Vienna, a collection of Aubel'druck prints by Aubel and Kaiser of Cologne, &c. Great Britain is represented by Brownrigg of Dublin, Hedges of Lytham, and H. P. Robinson of Tubridge Wells; in the latter case, the pictures exhibited are those that won the "Good Taste" medal, Vienna 1873, and are the property of the Vienna Society.

Lord Lindsay.—It is gratifying to learn that Lord Lindsay is again comparatively restored to health after his expedition to the Mauritius. The press of work and excitement connected with the observations of the transit of Venus, together with the unhealthy climate of the island, combined to throw his lordship into a violent fever, and for some months his health has been such as to give cause for much anxiety among his friends. A return to England was not permitted for some months after his arrival in Europe, a prolonged residence in Italy being insisted upon by medical men. We are glad to hear, therefore, that Lord Lindsay has returned so far to his previous state of health as to take part in a fête prepared in honour of his return by the Conservative working men of Wigan, which town Lord Lindsay has represented in Parliament since the last election. We are informed that many thousands of people thronged the streets to welcome him back after his tedious, though successful, journey to view the transit of Venus, while bands of music paraded, and the church bells were set going. The horses were unyoked from his lordship's carriage, and this was drawn through the town to Haugh Hall, the residence of his father, Earl of Crawford and Balcarres, amid the cheers of the people.

PRACTICAL PORTRAIT PHOTOGRAPHY.

By William Heighway.

Chapter V.—Colloion.

Although so many samples of commercial colloidion are very excellent, and, perhaps, from the large quantities made up at one time, of more reliable and even quality than the operator can make up for himself, I think it certainly not a waste of time for him to learn how to make it for himself. Should I even advise the student to procure for his early use a good sample of commercial colloidion? I should yet think he was not to know of what it is composed, and the nature and properties of these several ingredients.

Colloidon is made by dissolving pyroxyline or gum-cotton in a mixture of ether and alcohol. Pyroxyline is insoluble in water, alcohol, or ether, but with regard to the last-mentioned, many samples contain a percentage of alcohol; in these pyroxyline is sparingly soluble, but in alcohol and ether, of almost any proportion, it dissolves quite readily. A mixture of about equal parts is generally adopted in making colloidion for ordinary use. Certain iodides and bromides are added to excite or sensitize the colloidion, the iodides and bromides of ammonium, cadmium, and potassium being those most generally used—all, except potassium, being readily soluble in colloidion. Colloidion may
be "iodized" at the time it is made—that is, sensitized by the addition of the iodides and bromides according to the formula by which you are making it—or it may be kept "plain," to be iodized as you may require it.

Plain Collodion is made by adding ten or twelve grains of pyroxylene to every ounce of alcohol, and when it is well soaked, adding an equal amount of ether. The cotton may not entirely dissolve, nor is this an evidence of a bad sample of cotton. When the collodion is settled perfectly clear it should be filtered through filtering-paper or cotton (it being advisable to cover the filter with a plate of glass to prevent evaporation as much as possible), and preserved in a cool place.

The Iodides and Bromides used in the manufacture of collodion have various effects on it—those of an acid reaction, such as the iodide and bromide of cadmium, having the tendency to thicken and glutenize the collodion, tending to retard its setting on the plate, but giving a depth and richness to the negative; while the alkaline iodides and bromides, as those of ammonium and potassium, have rather opposite effects. They tend to render the collodion, in time, more liquid, and, liberating free iodine, give the collodion a sort of sensitiveness; they, however, give the required intenseness quickly, and cause the collodion to set rapidly.

The Sensitized Collodion requires care, cleanliness, and some little intelligence in its preparation, together with the proper purity of the chemicals used. The reader, if he has studied photographic literature to any extent, will have noticed that almost all writers differ in the proportions used in portrait collodion; and to a great extent in the iodides and bromides used; but a great number, if not a majority, seem to agree that the proportion of three grains of the bromides and five of the iodides to an ounce of collodion gives the best results. I shall not, therefore, be giving anything new in the formula I subjoin, though I have a lurking fear that I shall be looked down upon that I do not produce something more startling. To disarm criticism on this point in some measure, I may say that it is rather my intention to endeavour to be of use to the reader by furnishing him plain and reliable instructions than to give him difficult and doubtful problems to solve:—

</tr>
</tbody>
</table>

Grind these in a mortar, adding the alcohol, and as they are dissolved pour the liquid into a bottle of sufficient size for the whole. There should be no residue, if it has been properly done. The above are all readily dissolved in alcohol and ether, but where bromide of potassium is substituted for ammonium, the operation of dissolving it is more difficult, potassium being very sparingly soluble in alcohol, and scarcely at all in ether; but by uniting it with iodide of cadmium the difficulty is at once overcome. Grind the potassium fine in a dry state, and add to it, gradually, the iodide of cadmium until they are thoroughly incorporated; now moisten with alcohol until evaporating, it leaves behind a snow-white paste. Continue to add alcohol and grind, pouring off, after each addition, into the bottle until all is dissolved. When all the iodides and bromides are dissolved, the ether must be added a little at a time, the mixture being agitated before each addition of ether. When you have added all the ether, filter this mixture through filtering paper, through which it should run clear and easily. You can now add the cotton, tearing it up into little tufts. A little shaking will aid in the dissolution of the cotton. There may be a tritifying sediment of cotton, but this does not greatly matter. When this has settled perfectly clear, as it should in a day or two, it will be improved by an addition of some old collodion of the same formula, and will continue to improve with age.

When this collodion is poured on the plate, it should flow perfectly smooth, and be quite transparent. The plate being well dusted, and carefully guarded from dust which may (but shouldn't be) flying, the film should be soft, and free from ridges or lumps; but as the ether evaporates, leaving the alcohol in excess, the collodion will show signs of glutinizing, setting on the plate in lumps and ridges. The remedy is to add ether in the manner already described, until these ridges cease to appear. Fill ether the added ether as soon as possible.

The collodion, when first made, should be of a lemon colour; a dark red denotes too great acidity, and this may be neutralized by the addition of half a grain of bicarbonate of soda; but it were preferable, when it is too acid, to reject it, and seek purer chemicals.

In flowing a glass plate with collodion, the residue should be poured into a bottle kept for the purpose—not the "bottle from which it is poured." All bottles holding collodion should be kept well stoppered to prevent evaporation. To flow a plate, stopper the bottle, and take another to receive the surplus collodion from the plate; and that, without agitating the plate in hand, the young student will find is no easy matter, but he will manage it with practice. Do not get into a clumsy way of doing it at first.

The Practical Printer in America.

XXVI.

Finishing the Prints.

When the prints are mounted, all spots are to be touched out, and the high-lights in the eyes, &c., are to be placed in, as will be presently shown. It is not at all necessary to wait until the cards are dry to do this, but, on the contrary, it is perhaps better to touch the spots out while the cards are damp, so that if an ordinary roller is used the prints can be rolled while a little damp, and a better polish is thus secured.

When the beginner commences this work on the prints, he will think, if not before, see the importance of thoroughly dusting the negatives while printing, as the neglect of it will have occasion him considerable trouble, as well as the final result not being so nice as it would be if there were no such places to be touched out.

For this reason I have often thought that if the beginner was served as I was when I commenced to print it would be a good thing: it was to assist at printing on one day and the next to assist at the touching of the prints, for the space of a fortnight or so: and thus he would learn how much trouble was saved by a little care being taken in the first place, and a valuable trait towards making a good printer would be early acquired. But even if the greatest pains were to be taken in the dusting of the negatives, there are instances in which it would not prevent some places from printing—said places being in the film that is on the glass, occasioned in some of its manipulations, such as the varnishing, or by some defect in the glass itself, either scratches, bubbles, or something of that sort.

It will be seen that the better printer will take pains to be occupied in the touching out of these spots that I have, in a previous chapter, recommended not to "touch out holes" in the film any larger than what is necessary, and also where there are scratches, whether large or small, to print the negative either under one or two ground glasses, and even sometimes a tisue-paper, so that such places will not show any more in the resulting print than what is really necessary.
manipulator tries to assist him (the printer). A very noted New York photographer once said to me: "In my gallery, the object of those in each department is to assist each other as much as lies in their power by doing their work so that they will not have to rely upon the person or persons whose duty it is to do the next in routine to cover up their defects; for there is always enough of their own work to do, without doing any more of another's than what is absolutely necessary."

There is no small amount of work to be done by the lady in touching out the absolutely necessary corrections on the prints—there is no one who has ever tried to touch out can tell for a certainty, it being likened unto the work of a negative-toucher, both of them being more or less severe on the eye.

Any good brush, of a suitable size and with a good point, will answer for this purpose. In the mixing of the colours, which should be done every day, proper attention should be given to obtaining the same tint as the tone of the print indicates to you, so that the touched-out places will have the same appearance as the rest of the print. Water colours are used, India-ink, yellow and red colours predominating in the mixing, according to the tone you desire, which is generally of a reddish tint.

In applying the colour to the prints as it is now, they will dry dull, and when looked at obliquely these dull spots will appear as if there was a piece of dirt on them, a good glass to the print everywhere except where this colour is applied. To obviate this, a liquid solution of gum-arabic (made by dissolving the gum in as little water as possible) is mixed with the colours in such abundance as to give a good gloss to the prints when they are touched.

More often, instead of dissolving gum-arabic as described above, a lump of the pure gum is wetted with the tongs and rubbed through the brush, and the remainder of the lump is stuck to the pallette upon which the colour is to be mixed. In touching out, in case the colour after a while shows no signs of the arabic, then first rub the wet point of the brush on the lump of arabic, and then take up some of the colour and proceed to touch out the spots as before. The use of the arabic makes the colour a trifle more difficult to be touched-out, but will white you not notice it. A glass of clean water should be near at hand for you to wet your brush in and to cleanse it when necessary. The beginner in touching out with the brush and colour should be careful and not touch too heavy as well as too light, and never leave a spot unless the colour applied gives the same dark tint as the surrounding places, and he should not touch out a larger spot than what the spot really was, experience will tell him what is to be touched out, and what is not.

All dirt spots (i.e., light spots on the prints which are usually caused by dirt adhering to the varnish of the negative) should be touched out wherever they occur. The most noticeable places are in the cravat, face, background, &c. The unevenness, if there is any, of the retouching should also be glanced at—i.e., those places on some parts of the face which are lighter than the surrounding parts caused by the pencil of the retoucher taking too heavily.

I mentioned above about placing the high-lights in the eyes, and as the beginner may not know what I mean by it I will here explain. In many prints the eyes, owing either to the carelessness or ignorance of the operator, have no high-lights in them, and when such is the case they should be placed in each eye, as the proper place, by the brush, upon which a little white paint (water colour) is dissolved. The greatest experience is required to do this as it should be done, and the apprentice should always attempt it on his own responsibility until he has been thoroughly taught how and where they should be placed. In many cases the high-lights should in a measure be touched out, and all other reflected lights should be removed.

A common lead pencil of a medium grade of hardness is used for the purpose of modelling the face, as well as touching out the slight spots that are in the face, draperies, &c., whether occasioned by the retoucher in touching the negative, or by the printer in printing them. The Siberian graphite, No. 2, H. B. pencil, I have used with very good results. A good, not too sharp, point is made, and a slight touch of it will very neatly touch out the thin and long dirt spots, and in modelling, both in the lights and shades, it is capital. There will not be enough difference in the tone of the pencil-mark and the colour of the prints to cause any attention from this source, unless the places are larger than the head of a tolerably large common pin. The pencil very often makes the lines a little sharper and more defined than a brush, therefore it is used considerably, when it can be, with good results. For diving in between the shadows in the cheeks, and filling them up (not too much), and touching out those dirt spots which may happen to show on the high-lights, and in all places where only a very slight touch is required, the pencil is much better than the brush, as it will make a much better mark.

To ease the eyes in touching out the minute spots a large magnifying-glass is placed conveniently in a sort of a vise, by means of a suitable rod which is attached to the glass. This glass is placed at some six inches from the prints, and the person touching out can not only do the work better, but the trying of the eyes is in a great measure prevented. A little flesh-wash is given to the cheeks and lips of the ladies and children with good effects.

NOTES ON RETOUCHING.

Our Chicago contemporary continues the useful articles on this subject.

Freckles.—Experience teaches that negatives requiring much retouching upon every part of the face will never produce thoroughly artistic prints, and a negative that will become sufficiently smooth by working only upon the lightest and nearest portions, leaving the receding parts delicate and shadowy, will produce a face of wonderful relief and life-like brilliancy. The class we are now considering seem to baffle our attempts at perfection in this respect by forcing us to carry our work far beyond the desired limits.

Of course, good taste and ability in the operator may, and often does, greatly reduce our work, by throwing forward the focus on the face and producing a proper detail in the shadows. But to be sufficiently comprehensive we will suppose these negatives under consideration need very much retouching to make them smooth. The first work put upon them is the most difficult and important, that of touching out the freckles, and requires the aid of a magnifying glass, until every one, however minute, has disappeared. To do this the utmost care must be observed not to use too great force with the pencil, as no amount of after-work can make a smooth surface if coarsely done this first time. No stroke of the pencil should be observable except in effect, and the old adage, "The more haste the less speed," was never better applied than in this work. After the freckles have all disappeared, lay aside the glass, and, from a sufficient distance to enable the whole effect of the work to be seen, proceed to fill up the larger spots caused by the uneven surface the previous work has made. After this has been thoroughly accomplished it is usual to call the negative finished, and it is sent to the printer in that condition. No greater mistake is made than, "as will be seen by the careful inspection upon examination. If you possess two negatives of this class, that before retouching were considered alike, it is easily observed that smoothness has been obtained at the sacrifice of brilliancy and expression. That which was before retouching a curve of the forehead, or an indentation of the cheek, is now flat surface. The delicate shadow under the eye, on the shaded side of the face, has disappeared. The shade there under the nose had its share of freckles, and as a consequence the upper lip now looks swollen and unnatural. The mouth has lost its character,
the eyes their expression, the nose has become flattened; in short, a dull tameness pervades the whole face. To remedy these evils, the highest points of light and the darkest portions of the shadows must be rightly located, and their contrasts made as great as in the untouched negative. Even greater than this is admirable, if the original picture be flat enough to make such treatment desirable. Then we can more justly consider the negative retouched, and deliver it into the printer's hands with a better grace. In carrying out the above method, I would impress upon my readers the importance of preserving the same order of work as here given.

Our next subject to be considered will be the more diversified ones.

Copies.—Of course negatives of this class may possess any of the faults already described, and require the treatment therewith given. But the ones most frequently met with, and which I wish to dwell upon most, are those possessing no contrasts whatever; the face, drapery, background, and accessories being void of bright light or deep shadow, and possessing the same tone throughout. Of course it is not possible to make perfect negatives out of these; but it is possible to so improve and renovate them that their faults will be but lightly dwelt upon.

To begin, then, with a negative of this kind before us. The face, hands, and white drapery (if any there be) must first receive attention. After the surface above them is ground, their entire limits must receive the powdered crayon of the method already described, taking care to exceed the limits, or to omit any portion within them. Pass the crayon stump lightly to and fro until no streaks are discernible, and the surface has received all the crayon it will contain. If very great opacity is required, pulverized blue or pink pastel is superior, as possessing a desirable colour and great body; but from that we descend to No. 5, 2, and 1 Conti Crayon, according to their depth of shade, and bring quite hard; and as but a small amount will adhere to the ground surface, it is most desirable where the picture needs but slight raising of tone. After brushing away the residue we proceed with the pencil to smooth up the face, taking each feature separately, raising the light upon it as much as it will bear, and yet be a correct likeness; making the most of the minute in places that helps the idea of its correct form, brightening the eyes, making the division-lines sharper between lights and shadows; in short, bringing out the features distinctly that were suggestions in the original. The degree to which this can be carried must be learned by experience. The beginner will be sure to overdo it, and produce an unnatural picture. But as the prints show less of this than the negatives, it follows that a little intensifying of them becomes a necessity. After working upon the face until sufficiently smooth and well defined, the hands and drapery must receive attention. The fingers must be retouched as carefully as the features of the face, and the folds and detail of dress be well brought out. Care must be observed if lace or embroidery appears about the throat, not to trace it in the negative, but to give the features their natural tone by contrast you should make the face seem more inconstant than before. Next the background, which in this case is supposed to be undesirable, being too light, too dark scratchy, or too near the colour of the face, we wish to improve upon. First, entirely blot out the original background by covering the unvarnished side of the negative with an abundance of Conti Crayon using a small brush upon the outline of head and figure, and larger one for the remaining space. Now make a print or impression of the negative upon silvered paper, cut out the figure carefully, and when a perfect print is made possessing a white background, lay this shield over the figure, and shade the remaining portions to any desired tint, remembering that the background must be darker than the lights of the face. If it is desirable not to show the hands, a very pleasing picture can be made by vignetting the figure, besides stopping out the background.

Then, if the face is too dark to look well with its surroundings, place the back light, or part of the face, head, and hand, a small portion of the figure, exposing the remaining portions to the light until shaded quite dark.

I am aware that these suggestions belong to the printer, somewhat. But as we cannot learn too much of each department of our art, my friends will pardon the digression, I trust.

A PHOTOGRAPHER'S EXPERIENCES IN THE LIBYAN DESERT.

BY PHILIPP REMLE.

About five miles west of Gæs Dachel there was to be found the ruins of an Egyptian temple, the stones of which, so far as they were apparent, were covered with hieroglyphics in a well preserved condition. The heavy sandstone blocks of the roof had been thrown down, presumably by an earthquake, but the walls and inner spaces seemed to be passably perfect, so far as one could judge in their buried condition. Acting on M. Rohlf's instruction, I caused this temple to be photographed between the 19th and 25th February. In this way I was enabled to execute some perfect photographs, and the reproductions of the hieroglyphics proved of especial interest to those interested in the history of Egypt.

On the 18th March we took our departure from Gæs and proceeded to the Oasis Chargheh, the journey occupying five days over a most miserable bit of desert, and we were heartily rejoiced by Dr. Schweinfurth, who had occupied Chargheh. The celebrated temple at that place took up all my time on the following day, and I had little to spare, for our stay was limited to a couple of days. The hieroglyphics covering the whole of the walls had to be taken in portions, and a large number of plates, therefore, was necessary for the purpose. My tent, fortunately, I was able to set up in the shade, otherwise I should have had a great deal to worry me. On the following evening my task was finished, and I had secured thirty negatives. I was also fortunate in obtaining a very fine landscape picture of the oasis in the vicinity. As regards reproducing hieroglyphics in the camera, I should mention that these, in order to come out plainly in the photograph, here we were heartily rejoiced by Dr. Schweinfurth, who had occupied Chargheh. The celebrated temple at that place took up all my time on the following day, and I had little to spare, for our stay was limited to a couple of days. The hieroglyphics covering the whole of the walls had to be taken in portions, and a large number of plates, therefore, was necessary for the purpose. My tent, fortunately, I was able to set up in the shade, otherwise I should have had a great deal to worry me. On the following evening my task was finished, and I had secured thirty negatives.

Our last desert journey from Chargheh to Esneh on the Nile, where we arrived on the 31st March, put our patience and endurance to a hard test. The hot Charmin wind had already commenced, and had a most relaxing effect upon us, especially on the first day. The thermometer showed an atmospheric temperature of 84° Reaumm. Unfortunately, too, some of our comforts had been exhausted, and among others our stock of wine. Our camel was almost broken down, and it was only with the greatest difficulty that they pursued their laborious course.

On the 8th March we first became aware of the vicinity of the Nile from an appearance of smoke in the horizon in an easterly direction. The smoke proved to come from a sugar factory, and it was with the loudest cries of joy that we greeted this first trace of civilization. Every feeling of fatigue vanished in a moment, and all of us pressed eagerly forwards. But our goal was still a long way off, and it was not until the next evening that we arrived in sweet Esneh.

* Continued from page 122.
The well-known temple of Eme Android is almost wholly buried, and is only the forecourt that is exposed. By reason of the very weak illumination of the place I only secured a serviceable photograph after much trouble. I gave an exposure of 15 minutes, and the high temperature was fatal to many of my plates.

In Thebes, also, where we rested for a day on our return journey to Cairo, I was fortunate in securing some interesting pictures of relics of ancient Egyptian monuments. The great heat had, however, an injurious effect upon the photographic manipulations, and it was only after much trouble that I finally secured some good negatives. At Thebes my photographic labours ended.

The winter of 1875-6 in the Libyan Desert, as also in other parts of Egypt, was extraordinarily cold. Even in March, when the temperature is generally of tropical nature, we had very few days of very hot weather, and it is to this circumstance that I attribute, in great measure, the success that attended my efforts.

In very high temperatures the collodion was generally the chief source of failure. The Beyrich instantaneous collodion, which I took with me, is rich in alcohol and water, and while it worked well under normal conditions, it did not dry uniformly upon the plate, when the weather was hot. The upper and thinner side of the plate became too dry before the lower and thicker margin had done draining. This, of course, gave rise to many defects, and every plate exhibited the well-known blue margin. By adding an appreciable quantity of ether to the collodion, the latter showed a good deal of improvement. The film upon the plate then set more quickly and uniformly.

In this way a thinner and less sensitive film was produced, but this was a matter of minor importance. According to my experience, therefore, I should recommend the employment, in a dry, tropical climate, of a collodion containing a minimum of water, and of a quick drying ether—full nature.

In the very clear, transparent atmosphere of the Libyan Deserts, the contrasts of sunshine and shadow were much more considerable than they are with us in Germany. This glaring illumination of the scene is to be found in all my pictures; it is not hardness, but it is remarked, but a true reproduction of nature. A desert landscape appears to the eye of the observer exactly in the same way. As I had no photograph with me, unfortunately, I was unable to test the intensity of the light from time to time; but it is certain that the shadow I was able to produce, if I had occasion to print some negatives at Dachel. As a rule I gave the same exposure as I should have done in Germany in summer time. The difference in temperature during the day and night had, however, a material effect, as may be readily understood when it is mentioned that the thermometer at sunrise was often 35° Reumurr, while at 2 p.m. it marked +18° R. in the shade. That cold chemicals work slowly is well known, and therefore I had to regulate the exposure not only according to the nature of the object and the way it was illuminated, but also according to the temperature at the time being. If the photographic tent stood in the sun, as was usually the case, the temperature inside was, on an average, 10° to 12° R. higher than in the open air.

Very annoying in my photographic work were the masses of flies that swarmed everywhere from the beginning of February, and I was attempting portraitures. My brown native models were never very clean; they all possessed a shiny and greasy appearance, and evidently had a great abhorrence to washing themselves. My models attracted the flies in numbers, those settling upon their faces, and especially about their eyes, nose, and mouth. Not only, therefore, were all sorts of grimeux made, but the people wore rarely quiet during the sitting, from the insects teasing them so. I used, therefore, to begin work as soon as possible in the morning, before the flies began to be worrisome.

The few words necessary to warn my sitters to be steady were easily learnt, and I found both men and women very docile and attentive to my instructions, keeping the eyes in the proper direction and the head steadily to the rest. Generally, however, I employed one Sheikh Mohammed Daub as interpreter, for he spoke French with tolerable fluency. When the flies did not cease very much, the sitter sat quite still, and it was only the Barber of Dachel, who was so severely enjoined to be still that he became terribly frightened over the whole business, and shook in time making. Running, or if the flies were very numerous, the plates had to be carefully protected in drying, for, obviously, insects walking over the film during desiccation inevitably destroy the picture.

The water at hand for use, which I obtained from the different wells and springs, was for the most part very impure, and it was only the spring at Farafrah that yielded almost pure water. The water from the Dachel Oasis contained much iron and salt. All the springs at Dachel were warm ones, the temperature of the water varying from 30° to 36° R.; and, on standing, flocculent iron matter settled down. The iron developer prepared with this water acted all right when first poured over the plate, but as soon as the image began to appear, a white cheese-like precipitate was formed, which partially adhered to the film, and could only be removed by very energetic washing. Sometimes this phenomenon was so marked that it injured the pictures. In such cases there was nothing left but to purify the water first of all with nitrate of silver. The water was mixed with a little nitrate of silver solution, sunned for a short time, and then filtered, after which it could be employed for the preparation of the developer. The operation was a very elaborate and tedious one, but it was the only way to get good results.

In the Charch Oasis I found most of the springs contained salt, although, singularly enough, there was in the neighbourhood of the temple a spring of very fine pure water.

The Nile water, renowned throughout the whole of Egypt for its purity—or, as the inhabitants term it, its sweetness—was after filtration found to be very suitable for the preparation of solutions. It was necessary, however, to draw the water direct from the stream itself, for that taken from canals fed by the Nile was, on the contrary, very dirty, and often contained an appreciable amount of salt in solution.

[The publication of this last portion of M. Remond's interesting diary has been delayed for some reason unknown to us, and we have been unable, therefore, to supply our readers with it before. They will be glad to hear that the Viceroy of Egypt has just presented M. Remond with the order of the Medjije, in recognition of his valuable services.—Ed. P.N.]

"TOUGHENED GLASS."—Lieutenant-General Sir Henry James writes to us as follows:—"Under this head you refer to a process by which glass is made in such a manner that it entirely ceases to bebrittle. But I think it is to the account of, apparently, a similar discovery in the time of Tiberius by Phyn, Dion Cassius, and Suetonius:—"In the reign of Tiberius, it is said, a combination was devised which produced a flexile glass; but the machinery of the artist was totally destroyed, we are told, in order to prevent the value of copper, silver, and gold from becoming depreciated."—Phyn, B. xxxvi., chap. 66. According to one account, Tiberius ordered the artist to be put to death. I hope M. Francois de la Bastie will reap the reward which the Roman artist ought to have received, instead of death."—Times.
SHORTENING EXPOSURES.

A COMMUNICATION from Mr. Werge, which we print on another page, gives details of some interesting experiments suggested by our recent article on obtaining increased sensitiveness in the wet collodion process. Before referring to the results obtained, we may remark that we always regard with great interest, and attach considerable weight to, the experiments and results of photographers of experience and eminence—Mr. Werge, one of the early portraitists, who has passed through the entire curriculum of photography, from the Daguerreotype downwards; one who, whilst steadily working in the recognized practical paths as a professional photographer, has always had a keen love of exploring the diverse side-paths as an experimentalist, being familiar, practically, probably, with every process and modification which has been suggested in the art, and who now, in devoting some time to photography, brings to bear the habits and experience of a professional photographer and the zest of an amateur. We make these preliminary remarks because the calibre of the experimentalist materially qualifies the value of the experiment, and we regard such work from such men with especial favor.

Mr. Werge sends us examples and details of experiences in two of the directions to which we referred in our recent article: the use of diffused light as an accelerant, and the use of nitrate of uranium in the nitrate bath for the same purpose. We will take the latter first. From the experiences of Captain Abney and Colonel Stuart Wortley, and our knowledge of the behavior of the uranium salt under other circumstances, we were led to hope that a valuable accelerating agent was available for photographers, and to urge its further trial. In Mr. Werge's hands the result is miserably disappointing, nor is the result deduced from one hasty series of experiments. The attempt to utilize nitrate of uranium in this way is not new with Mr. Werge. He has before worked in the same direction, always with the same result. The rejection of the suggestion induced him once more to repeat the experiments, and he sends us details and examples of the results. Nothing could be fairer than the mode of conducting the experiments; nothing, apparently, more conclusive than the results. A plate was coated with a collodion of known sensitive character, and, after coating, divided in the middle: one half being then sensitized in ordinary silver bath, then, and the other half in a similar silver bath to which nitrate of uranium was added in the proportion of ten grains to each ounce. They were then exposed simultaneously under the same conditions, and developed in similar manner. The half excited in the ordinary silver bath yields a good, well-exposed picture; that excited in the uranium-treated bath is hopelessly under-done, certainly not half enough, probably not one-fourth, in effect, as much exposed as the other half. The experiment was repeated, substituting a new unsensitized silver bath for comparison with the new one containing the uranium salt. The discrepancy in exposure does not appear to be quite so great: the bath with uranium yields a poor, under-done negative, whilst the new bath without addition yields a fine, well-exposed picture. In a third experiment the old bath, in good condition, was tested against a portion of the solution with nitrate of uranium added. The contrast here is as striking in the first experiment. In this case the discrepancy in exposure does not appear to be quite so great: the bath with uranium yields a poor, under-done negative, whilst the portion of it which has been treated with uranium is a miserable failure, under-done beyond estimating.

Now, here is a perplexing paradox! Two gentlemen so experienced and able, both as practical photographers and experimentalists, as Captain Abney and Colonel Wortley, find the addition of nitrate of uranium to the silver bath a definitely accelerating agent. Mr. Werge, as non-experienced, finds it not only not an accelerator, but an unmistakable and serious retarder. That each of the gentlemen named has obtained the results described there cannot be a question; and as no result can arise without a cause, there must be, in some part of the operations, a serious variation in the conditions. What it may be we are not at this moment in a position to state; but we may refer to an analogous case. The addition of nitric acid to the silver bath was for many years regarded as having a seriously retarding effect; and so it doubtless had under the conditions in which it was employed: that was, with a simply iodized collodion. With the free use of bromides in the collodion, nitric acid is not only not retarding, but, under some circumstances, possesses actually an accelerating effect. It has been suggested, then, to note in what points the conditions of working in the case of Colonel Wortley and Captain Abney vary from those of Mr. Werge, in order to account for the discrepant results recorded. That some variation exists we assume as certain; and we are only plentifully declaring the thing as it is in insisting upon it. Nothing could, perhaps, better justify Colonel Wortley and his committees than the results to which we have been calling attention. Half a dozen capable gentlemen, testing, first separately and then together, would more readily trace the causes of such discrepant results than half a hundred working independently and without collaboration.

The definite confirmation which Mr. Werge is able to adduce, and the advantage of pre-lighting in a satisfactory as the uranium results are perplexing. The use of diffused light to supplement an enforced curtailment of the exposure proper, whether from movement of the sitter or other cause, seems to possess advantages over pre-lighting, on the ground that it is more often required to compensate for such curtailment, than as an addition in case of premeditated curtailment; otherwise we think that on theoretical grounds pre-lighting is preferable to after-lighting. But this is a point which might be definitely determined by a committee of capable men, if such could be induced to undertake an examination of all the methods proposed of late years for reducing exposure. Failing this, the special effort of individuals in testing methods and recording results, in manner similar to Mr. Werge, will form most important contributions to a final settlement of many questions of vital interest in the progress of the art.

ASPHALTE AND BITUMEN IN PHOTOGRAPHS.

The use of bitumens of Jutland in producing photographic prints has almost passed out of notice amongst photographers. As, however, the question has more than once recently been raised by correspondents as to whether the process had not sufficient claims for more general practice, it may interest some of our readers to be reminded of the
treacherous character of bitumen as a pigment. The
Atheneum says:—

"An artist of distinction expresses his surprise at learning
the other day from his colourman that the old practice
of using that extremely fallacious pigment, asphaltum, is not
only not discontinued by painters, but is as common as ever.
We are compelled to endorse the remarks of our informant
on this subject, that these collections of paintings are well aware that irreparable and
constantly increasing mischief has attended the employ-
ment of asphaltum. A large proportion of Wilkie's later
productions have been ruined by abuse of the facilities
which attend the use of asphaltum. The material, unlike
most other pigments, seems never at rest, for a slight
increase of pigment renders it opaque and unadap-
table to useful change; hence it has been the occasion of
the most curious deception under the guise of art,
and this occurs again and again, separating the
material from its neighbours, to the ruin of both.
Decrease
of temperature, on the other hand, causes it to shrink,
and ultimately it appears to shrivel to a condition approaching
dryness, and it is then apt to part from the canvas on
which it has been placed. The results are obvious in such
pictures as Hilton's 'Sir Calpe rescuing Serena,' one of
the artist's best works, formerly shown in the National
Gallery; and many people may remember that one of
Serena's eyes slipped over the cheek below it. The picture
had to be turned upside down till the wandering eye
slipped back again. One of Newton's pictures in the col-
lection of the Duke of Devonshire is in a disastrous state
owing to this cause; it is cracked all over. Nor does the
increase of pigment change in its original colour: it becomes
rusty as it deteriorates in other respects. Several of
Reynold's sitters are said to have contracted with him
that only permanent pigments should be used in their
portraits. We suggest that picture-buyers should imitate
Reynold's employers in this matter, and covenant that
their purchases shall be innocent of the bad material,
otherwise their investments may, in a few years, be
valueless."

UTILIZATION OF RESIDUES.

BY PHOTO-CHEMISTS.

In the following remarks on the above subject, so im-
portant to photographers, we wish, at the outset, to depre-
cate all criticism from a scientific standpoint.

To those who possess even the moderate amount of
chemical knowledge, these observations will be useless.
We are not going to write anything that is not already well
known, but our object is to explain a few chemical facts in as simple a manner as possible; to show their prac-
tical importance and value to that numerous class of hard-
working, practical photographers whose time is so absorbed
by their every-day work that they have none to spare for the
acquisition of chemical knowledge; and if they find,
as we trust they will, that a little careful attention to our
details will effect for them a considerable pecuniary saving,
our aim will have been fully accomplished.

Without further preface, we commence by pointing out
that the order of silver waste in photography is as follows:

1st. The development of the negative.
2nd. Fixing it by dissolving out the free iodide of
silver.
3rd. Washing the prints.
And, lastly, fixing them.

It may facilitate our explanation if we commence with the
simplest case of all, and deal first with the chloride of
silver obtained from the process of print washing.

Now, the first and most important point we wish to
explain to our readers is one of the fundamental laws of
chemistry, viz., that all simple bodies—or, as they are
called, elements—have a remarkable peculiarity, which is
that they unite to form compounds in certain unalterable
and fixed proportions. It is unnecessary to explain this
theoretically, but we will give a practical illustration of
it in the case of the metal silver of which we are now
treating. For the sake of brevity we must ask that our
figures be taken for granted.

Silver, then, is said chemically to have a weight or
combining number of 108; chlorine of 353; sulphur, 16;
iron 28. Now we can show our meaning so as to be easily
understood. Let us take the case of the process of washing
a print. The milky water is poured into a bottle and
some salt is added, and the result is that a white curdy
substance falls to the bottom. Why does this occur? In
this way:—The washing water contains free nitrate of
silver; the salt is composed of chloride of sodium. Now,
when these two substances are mixed, the result is no
longer nitrate of silver and chloride of sodium, but a change
takes place, and we find it to be nitrate of soda and
chloride of silver; which latter, being insoluble, falls to
the bottom.

Now for the lesson we wish to impress. This chloride
of silver has a fixed constitution. It is always the same;
no matter whether too much or too little salt has been
added, no matter whether it be summer or winter, whether
the water be dirty or clean, hot or cold, the resulting
chloride is the same, and consists of 108 parts of pure silver
and 353 parts of chloride; in round numbers three-
fourths of its weight will be pure silver, and the photo-
ographer who deals separately with his print-washing should
get approximately this value. If the return do not amount to at least two-thirds, either he has not received
the value, or he has allowed it to become mixed with some
less valuable material. But by a very simple process any
photographer who chooses to take the slight trouble involved
in keeping his print washings separately from the other
waste need not be at the mercy of the refiner. If he will
simply keep a jar or cask containing a pound or two of
scrap zinc, and a tap at about one-fourth from its bottom,
and run off the clear water by this tap after it has rested
all night, he will at length find a considerable quantity of
black powder at the bottom, which will be absolute pure
silver, but somewhat contaminated by the zinc. Let this
at intervals be carefully collected and soaked for a few
hours in a mixture of oil of vitriol one part, water nine
parts; and the remainder can be either converted into
nitrate of silver, or fused into the metallic state, or sold at
its actual value. The total cost of recovering ten ounces
of silver by this method ought not to amount to more
than one shilling. One or two cautions may be advisable.

1st. In pouring off the clear water from the jar or
barrel, it will be well to test it occasionally by adding two
or three drops of solution of salt to a tumbler-full of
the water. If this should turn milky, the conversion of
the chloride into metal is not complete, and the vessel
should be shaken, or its contents stirred, and again left at
rest for a day or two.

2nd. Under no circumstances should any fixing agent,
either cyanide or hypo, be allowed to mix with this or any
other residues, but they should be kept and treated
separately, as these agents dissolve the chloride freely, and
are not to be separated in so advantageous a manner.
This process is also the best for recovering the metal
from an old bath, and with ordinary care the actual loss
is almost inappreciable, while the resulting metal is
practically absolutely pure.

In our next we shall treat of the developing and fixing
wastes.

A CELESTIAL STUDIO.

BY D. K. GRIFFITH.
Shanghai.

It must not be surmised, from the title of these notes,
that they will embody any heavenly vision, or conjure up
for the amusement of the reader a fairy dream-land.
With this short prelude to what is matter of fact, I will
introduce you to a China-man’s studio in the “Far East.” There is a staircase to ascend, and you are at once in the reception rooms, adorned by a few dilapidated cane chairs, a circular Nippono table, a glass case containing a small assortment of very old portrait cases and frames of the cheapest kind; a mirror of common glass is suspended over the dirty mantelshelf, and reflects your visit in the most unprepossessing style of its kind. China-men and imbecile looking foreigners garnish the walls, and hang published libels of the art appealing to public justice against the growing depravity of photography, and seeming to wonder how long their spirit of patience is to be tried. But the visitor’s mind is utterly lost in astonishment while contemplating the heterogeneous display of coloured wonders. Miseraably vague would my efforts be to describe their amazing effect upon the artists’ visitor, nor shall I attempt it, so please to draw upon the fund of your own imagination. Nor is English literature overlooked, as we find a London Directory for the year 1840, which the enterprising proprietor has recently purchased at auction, and after a hard contest succeeded in securing for tis. 6 or about £2), which, considering its age, is a cheap copy.

So much greed and love of a cheap style is ingrained in the China-man’s nature, that it is not possible for him to lavish or even expend the necessary outlay in the fitting out of his premises. A China-man, when buying, must buy cheap, or at least something under the market prices, to feel satisfied with his purchase. Saving a few cents is his object of greater importance than getting a really suitable and becoming in the exterior arrangement of his studio, the accessories, and apparatus, a too plainly perceptible cheap style pervades, and, in consequence, their studios are but little encouraged by resident foreigners, their only patrons being sailors from foreign ships in harbour, or occasionally a foreign merchant’s clerk sitting for a “sppos.”

Indeed, so exclusive is their business with sailors, that the China-man will ask the question, “What ship you belong?” —if you “belong” as captain or engineer? —or “belong” chief sailor man?”

Many of them do a very good business, and, with the natural characteristics of China-men, plod on with praise-worthy perseverance, imitating their more able and better-supplied foreign brothers in every little novelty that may appeal to the time; and often those efforts are very grotesque.

The native artist has little support from his countrymen, and from this cause none are to be found away from foreign settlements. Some few enterprising Cantonese have tried to push business in a few of the large towns of the interior, but were obliged to withdraw, from the hostility of the natives, who display their repugnance of the art by various petty annoyances upon all occasions, sometimes resulting in serious consequences and danger of life. In my own case I have had my chair torn to pieces on the road, my coolies beaten, and my camera broken; but, owing to the wholesome dread of a foreigner entertained by the natives, I happily escaped with only a display of stone-throwing; in the case of a China-man he would have fared worse. The whole series of graphic manipulations is due to a strange belief, which it is impossible to eradicate, that the photographic image is the soul of the original, the withdrawal of which from the body very naturally producing death. This tragiend may not take place for a mouth or more, but I have heard two years given as the longest time the photographed vic- sim can exist. Some few are to be found who avail themselves of the art, and indulge in a portrait of themselves and their families. In this case, great are the preparations bar the sitting. Their number one (best) clothes are dis- patched by a coolie; they are put on in the studio with such care and more talk; the victim seats himself, spread-

**Tails vary in value, the average in Shanghai being six shillings.**

**A term applied to all on sea of petty larceny or swindling.**

*The photographic news.* May 28, 1875.

*If the sitter and the artist are natives of different provinces, the conversation is conducted through the medium of an interpreter; or if both are familiar with “Pidgen English,” it is carried on in that peculiar idiom. For illustration and convenience we will conduct it in the latter way.

During the considerable time occupied in the sitter’s preparation and toilet operations, the artist has been channelling himself, and pondering possible profit, comfortably reposing on a Singapore reclining chair, with his pipe and fan. The China-boy approaches, when the learned professor of the black art extends himself at greater length, and comes out with the expressive words “What thing?” The boy explains that the sitter is ready for him, when he deigns to take the purely mechanical discovery, with cat-like steps he enters and confronts his visitor. Both bend low in the characteristic salaam, meeting their hands together as required by their etiquette. A short altercation then begins as to which of them is to reseat himself first. At length their politeness decides that both are to be seated at the same time, cups of tea are brought, and each takes the same number of sips. Their introduction being gone through, business commences by the artist putting the quaint question:

“How fashion you wante that picture? Wanté like like, or number one handsome?”

The unintimated in “Pidgen English” is to understand that he desires to know if the sitter requires a nice picture, got up regardless of expense, or the more understanding, of himself on his own terms, with a choice of his own choice. The gentleman in this case, we will suppose, desiring the latter, the artist rises, and prepares a glass. The interval is usually filled up by questions of so personal a nature as to be most offensive to foreign ears, but with them perfectly decorous, and in accordance with the rites.

The portrait taken, the “artist” returns with the satisfactory announcement that it is “number one,” and “too much like.” In the language of the place the sitter asks him to “pay my look see.” But firmly, though politely, the “artist” declines by the admonishing phrase: “My no can suppose you spolre him.”

This being considered conclusive, the delicate question is asked: “How much cost twelve picture?”

*Artist. —“Fire döllor.”*”

*Victim. —“My think five dollar belong too much.”*”

*Artist. —“How fashion belong too much?” You pay my all the same other piece man. My no wanté squeeze you one cash. I suppose my squeeze you, my must lose face, and every man savey my do pidgen that fashion. No, my talké truse; five dollar belong custom.”*

All being eventually settled agreeable to their mutual
satisfaction, the sitter again changes his clothes, and passing by printing-frames and sundry other photographic paraphernalia, with a parting salaam he again takes the street, and entering his sedan chair goes on his way rejoicing.

DR. VOGEL AND THE ENGLISH ECLIPSE EXPEDITION.*

Our prospects are not brilliant. Since we have been in the Indian Ocean the weather has never ceased to be clear, and except upon the few days he has had no appearance of blue, but veiled, so that the photographic action of the direct sun is unfavourable, though I had, owing to the height of the sun, anticipated the reverse would be the case. Still more gloomy are affairs connected with the instruments. My invitation came from England, and I was informed that instruments would be placed at my disposal. Judge of my surprise, therefore, when, on unpacking, I found nothing but heavy, unmerely playthings. In the first place, I have no telescope, but only an ordinary six-inch lens, endowed with an awful focal difference, and without a camera. This lens, which is upon a stand, is to throw an image of the sun by means of a mirror which receives the sun’s rays. The lens, however, is in motion, and the mirror ought, therefore, to be able to follow its path, if the image is to remain reflected upon one spot, which is a matter of course in photography. The mirror ought, therefore, to be provided with a clockwork movement; but there is none fitted to it. My assistant is to turn the instrument, it appears, and is to practise so as to do it accurately.

Really one hardly knows what to think when one looks at playthings that have been made. The two members of the expedition from England have, of course, provided themselves better; they have telescopes with clockwork and all kinds of perfections such as are necessary to the successful accomplishment of the difficult task we have in hand. I compare myself to the stork, in Esop’s fables, that is invited to dinner by the fox, and finds itself unable to eat the broth set before him, in a flat dish, with his long neck, while the fox sits away at the service but undivided pleasure. So it may happen that my English friends, who have learnt from my writings how to photograph a spectrum, will be successful, while I may prove unfortunate. Unluckily, I shall be unable, like the stork, to have my revenge.

My only hope is that the Indian observers may have a chance to be unprovided, or that I may be able to borrow one from the German Transit of Venus Expedition, and for this reason I have telegraphed to Singapore, where the party is now occupied in making longitudinal observations. The stupidity of the whole business is that the Astronomer Royal in London possesses a suitable telescope, but he would not allow the same to be sent out, as the expedition is undertaken without his sanction.

I am already beginning to feel the effects of the tropical climate, the fearful heat, and the vapoury atmosphere. The sleep at night is quite a tour de main. Unfortunately, too, there are a great many ladies on board, and for this reason we are much inconvenienced. During my first voyage there was not a single fair passenger, and we slept on deck, on the table of the saloon, or anywhere else we chose.

To-morrow we arrive at Ceylon. For the first time I shall see tropical vegetation. We shall remain three weeks in the Nicobar Islands, and then proceed to Calcutta. Captain Waterhouse, of Calcutta, will be one of the observers. It will be a pleasure to meet him, as I know him personally, and he speaks German. Another gentleman, a member of the Berlin Society, M. Schirmer, shall also have the pleasure of meeting. I hope to meet M. Eschke returning from the Transit of Venus Expedi-

* Photographiche Mittheilungen.

tion, and if so, I shall take him with me as my assistant, for I have already permission to do so.

I think of remaining in India to the end of May, and returning to Europe in June.

I hope to bring some interesting pictures from Aden and India, which I shall purchase rather than take. In Aden very fine photographs 8 by 10 inches, mounted, can be purchased for a rupee; and at Suez the same may be had for a mark. The cost of unmounted prints is very much in vogue, and I think the custom would become popular in Germany. The photographer saves the expensive cardboard, which, if the print decays, is always lost; while the purchaser can roll up and transport his property more easily, and have it mounted as he likes. When it is borne in mind that the cardboard often costs as much as the picture, the matter becomes one worthy of consideration. The tearing of unmounted prints is easily avoided by the seller; pictures of the same kind are placed in a heap, and covered with a thick glass plate. In this way every purchaser could see them without touching, and we know how many pictures are spoilt by dirty fingers.

On board the Baroda, before Ceylon, March 14th, 1875.

Correspondence.

ANOTHER PHOTO-RELIEF PROCESS.

Sir,—In your issue of the 21st I see a patent has been taken out in the land of Stars and Stripes for a new photo-relief process. It may not now be out of place to give the outline of another and more valuable one worked out, I believe, by myself; it is as follows:—A transparency is coated with chromatized gelatine, and exposed to the light, the result being a relief in gelatine, the lights of which are represented by elevations, and the shadows by depressions. This relief is subsequently hardened, so as to stand a fair amount of use in printing. How the film is so hardened it is not my intention to particularly describe at present; sufficient is it to say metallic substances are deposited in the body of the gelatine, and means taken to prevent the swelling of the gelatine printing surface by materials repellant of water.

Those of your readers who may be acquainted with the Woodbury method will see many advantages in the above outline of a modification thereof. I merely write this to prevent anyone placing restrictions on the profession by patenting that which is now sufficiently indicated to prevent the possibility of it, and which ultimately shall, so far as I am concerned, be freely placed in the hands of those who may be inclined to use it. — Yours truly,

W. E. Barno.

Halifax, May 22nd.

SUPPLEMENTARY LIGHTING, AND URANIUM IN THE BATH.

DEAR SIR,—The remarks in your leader of last week, on "Uranium and other aids to increased sensitiveness in the work," induce me in hard words to give evidence of the advantages of supplementary lighting. As you will see marked on the print, the simultaneous exposure with twin lenses has three seconds with a supplementary exposure of three seconds more on one of the pictures. You will easily distinguish the one from the other, and observe the immense gain in detail, density, and delicacy. In short, the one is a useless negative, and the other is a usable one; always was, and am yet, a believer in the desirability of giving the proper amount of exposure through the lens to obtain the best results, and was consequently for a long time a sceptic in the advantages to be derived from either preliminary or subsequent exposure. Mr. Foxlee took great pains to make me a convert to supplementary exposure, and I thought I was converted, but as all my
Experiments in the winter months gave me more fog than increase of detail, I became a backslider, and relapsed into my old ways.

Short exposures are of great importance to me, for I make the difficulties of grouping and posing children my recreation. I employ the quickest lenses I can buy, and endeavour to have and keep my collodion, bath, and developer in the very best conditions; but notwithstanding all these advantages I find that simple exposure and developable conditions is not sufficient. It was only the other day I required five seconds to obtain a good picture, but my sitter was too restless to give me more than two seconds sitting. By after-exposure I made up the deficiency, and obtained a usable negative thereby. This induced me to make further experiments, and I am now thoroughly convinced of the efficacy of supplementary exposure, and I consider that subsequent lighting by any of the previously described methods is the best, perhaps the simplest, and one that involves neither outlay for new apparatus, nor loss of time in the one that I employ, which is simply to hold a piece of white blotting paper, or filter paper, before the lens, close to the hood, immediately after exposing on the sitter.

I do not think it probable that either the optician or chemist can reduce the ratio of rapidity to fifty per cent, or two-fifths, which light alone really does; and I would recommend all those who are anxious or find it necessary to work rapidly, to try after-exposure by the simple, ready, and inexpensive means I have described. I recommend subsequent exposure for the following reasons.

First, obtain the proper amount of exposure through the lens if possible.

Secondly, if you do not obtain the right exposure from the sitter, resort to subsequent exposure to supply the deficiency.

Thus, if five seconds are required to obtain a good result, and only three are given by the sitter, take diffused light for the other two, and so on, regulating the time of the subsequent exposure according to the time obtained from the sitter. I have generally found that the best results were obtained by giving about two-fifths of subsequent exposure, though as much as one hundred per cent. may be given with safety in cases of very short exposures on the sitter.

Nitrates of uranium in the nitrate of silver bath, as recommended by Col. Stuart Wortley, is not an accelerator. I have made experiments with nitrates of uranium in various solutions and emulsions, and have always found it a great deal slower than the silver salts in all forms, and a retardant. As in the cases of the addition of nitrate of uranium to the silver printing bath and collodion, so it is in the silver sensitising bath for negatives, the very reverse of an accelerator. Every grain of nitrate of uranium added to the exciting bath of nitrate of silver makes it more and more insensitive. It is years since I satisfied my own mind on this point, but I have recently made careful and important experiments, and send you the results, that you may satisfy yourself and your readers on that subject.

The examples sent herewith are all numbered and described on their faces, but I will here give you a detailed account of the manner in which I made my experiments, and I think you will admit that it would scarcely be possible to make any experiment of a comparative character in a fairer or more convincing manner.

First, I coated a plate with a known sensitive collodion, cut the plate in two afterwards, and excited one half in a known sensitive silver bath. The other half was excited in a new nitrate of silver bath with ten grains per ounce of nitrate of uranium added. Both halves were simultaneously exposed to the same light.

Result of No. 1 experiment—The uranium half as many times under exposed.

Secondly, I treated a plate in the same manner, and excited one half in a new nitrate of silver bath, and excited the other half in a portion of the same silver bath with ten grains per ounce of nitrate of uranium added. Both halves were exposed and developed at once as before.

Result of experiment No. 2—The uranium half still very much under-exposed, though the difference is not so great as in experiment No. 1.

Thirdly, I took a portion of my regular working bath, which was in excellent condition, and added ten grains per ounce of nitrate of uranium to it. Coated a plate with the same collodion, cut the plate in two, excited one half in the silver bath, and the other half in the uranium-nitrate of silver bath. Exposed and developed simultaneously as before.

Result of experiment No. 3—Urano-nitrate half vastly under-exposed, and the fallacy of the uranium accelerating theory fully exposed. In all the exposures the time given was ten seconds in a north but somewhat variable light, but that does not damage the results of the experiments, for in all cases each pair was treated exactly the same, and the results are in all cases immensely against the addition of uranium to the nitrate of silver bath as an accelerator. I remain, dear sir, yours truly,

J. Wason.

MR. SAWYER'S DOUBLE TRANSFER PATENT.

Sir,—I have just read in your journal of April 30th the conclusion of Mr. Sawyer's paper, respecting his new double transfer medium, and I notice that he does not say that he coats his single transfer paper with plain gelatine previous to applying the lac solution, as Mr. Spiller says in his 'paper that he (Mr. Sawyer) does. I have used since last October, for double transfer, single transfer paper coated with a solution of lac in ammonia. I did not think of any one patenting such an article, or should have published it in your journal. I see Mr. Spiller gives Mr. Johnson the credit of introducing reversed negatives. He must be mistaken, for Mr. Johnson certainly never claimed it himself, and he would if he had brought it out. Your respectfully,

E. H. D.

Boston, U. S.

[Mr. Sawyer's patent is not for the use simply of paper prepared with lac dissolved in ammonia, which was used many years ago by Mr. Johnson, but for double transfer upon a flexible impermeable support with an elastic surface. The use of reversed negatives is very old.—Ed.]

A BATCH OF QUERIES.

Dear Sir,—Your advice on the following will oblige:—

1. Will "rice-flour paste" do for mounting C.D.'s? If not, why not? I have heard that it is the best article to use for pasting paper work. It is nearly transparent, and, I fancy, will not turn sour so soon as other pastes.

2. I have always found my worn-out gold bath work well if I put the prints in without washing them in the usual way; while if I washed them first the bath would not tone at all. The pictures do not look so bright as they do when previously washed. What is the cause?

3. When I use nitrate of baryta in the negative baths, I find all the negatives, after fixing, look as if they still retained a trace of iodide of silver. A decided blue tinge appears when they are viewed slanting; but when viewed straight through, they appear as usual. What is the reason? Can (and ought) it be remedied, and how? Is it hurtful to negative in any way?

4. Is the following "wrinkle" known to photographers? If not, then it originates with me. To the sensitising bath (of twenty ounces) add a tablespoonful of whitening, and, when going to use the bath, shake it well up, and pour whitening and all into the dish. In a few seconds the whitening settles to the bottom, leaving the solution clear as pure water. Pour it off, and return bath to bottle in the same manner as poured out. Bath is always neutral, never discoloured, never requires filtering. The whitening cleans it of all impurities. Add fresh whitening when you add fresh silver.

[1. Yes: as well as any paste.]
Proccedings at Societies.

WEST RIDING OF YORKSHIRE PHOTOGRAPHIC SOCIETY.

The ordinary monthly meeting of this Society was held on Monday, the 3rd instant, at the rooms of Mr. J. W. Gouge, President, in the city of Bradford.

The minutes of the last meeting having been read and confirmed, Mr. G. Stolfferpe, Bradford, was elected a member.

There being no further business on the paper the question-box was opened; and the first question to hand—"How does the half-holiday affect the business of the photographers who now enjoy it?"—was laid before the meeting for discussion.

The Chairman remarked that as the Bradford photographers had tried the experiment, the meeting would doubtless be glad to hear the result of the trial.

Mr. F. R. F. O. stated that, so far from the practice deteriorating his business, he believed it to be a decided advantage. He himself invariably closed and went into the country, returning to his work the next day with, greater zeal, and he believed he had not lost any customers by it, as they all came on some other occasion.

Mr. Gunstone said they had found it to work satisfactorily, and were not aware of the slightest diminution of business.

He would be extremely sorry were the half-holiday discontinued.

Mr. Thompson also spoke in favour of the movement.

Mr. Wormald was of opinion that, if the holiday were granted, the operators thus benefited should make up the time on another occasion, though the average number of hours worked in a week should be taken into consideration. If a man was to be up work at four, he could not see the necessity for the holiday in such a case.

Mr. Broadhead fully recognised the necessity for the week-day half-holiday; and said that, although it was not a custom in Leeds, he had found it to his advantage to give each of his assistants a half-day weekly, though he did not close his places of business, but allowed each of the assistants the vacation on a different day. If, however, the Leeds photographers should arrange to close their respective places of business on one particular day, he would gladly coincide with the arrangement.

Mr. O'Gorman also spoke in favour of the movement, and said that an out-door operator did not require the holiday so urgently as the indoor workman. For the man spending the greater part of his time amongst the deleterious vapours of the dark room a little fresh air and recreation became a prime necessity. For his own part he should like to advocate closing for the whole day, as with most photographers comparatively little business was done except preparing for the afternoon's work, and a half-day was too short a time to go any distance. He should very much like to see the matter thoroughly discussed among the profession.

Mr. Wormald considered it was not necessary for a man to travel a great distance to enjoy a holiday or derive benefit from it. If a man had a garden and would dig in it an hour or two it would do him as much good as a long excursion.

The Chairman, on behalf of which he had been connected, said the system had proved highly successful. Patrons had often come in just at closing time, but when the matter was properly represented to them, they cheerfully acquiesced in the request to come another time.

Mr. Ratho entirely approved of the movement, quoting the saying, "All work and no play makes Jack a dull boy." If they wished a man to produce good work the holiday would have a decidedly beneficial effect, as there could be no doubt that if a man were overworkcd the quality of his work would necessarily deteriorate. If all photographers would combine, and unanimously decide to close their respective places of business on a given day, the matter would be easily managed; and when the public became aware of the custom they would accede to it.

Mr. Holgate suggested the advisability, as far as possible, of photographers avoiding having their holiday on the days when other trades had theirs, so as to afford the assistants on their holiday an opportunity of visiting the photographer's shops.

The Chairman suggested that as the meeting appeared to be unanimously in favour of the movement being set on foot, it might be advisable to appoint a committee for each town represented by the Society, such committee to consist of a principal and an operator, who should call upon the other members of the profession and solicit their concurrence.

The Secretary said the movement in Bradford had been carried out in a similar manner. A member of one of the leading firms in the town called upon two or three of the other photographers to ascertain their opinion on the matter. At the meeting of all being in favour, a committee formed themselves into a committee, and called on the various other members of the profession requesting their co-operation, and the scheme met with so much approval that there was not a single dissentient voice.

Seeing this question could not be definitely settled it was resolved, on the motion of Mr. Balmer, seconded by Mr. Ratho, that the discussion should be postponed, several of the members promising to see the others who were not present, and ascertain their opinion on the matter.

The next question from the box was—"Has any member tried bichromated glue for lining a bath?"

The Chairman said that, chrome alum not being readily obtainable, he had used ordinary alum, and found the dish perfectly waterproof, but the bath solution was much disorganised.

A Member said he had used a bath lined with wax dissolved in benzole, but had found it too brittle, as it left the dish in small flakes.

Mr. Balmer suggested that a little india-rubber dissolved in the bath would have a tendency to make it less brittle.

The Chairman had tried the last-mentioned method. He found the rubber solution did not spread evenly, but rose up in small lumps.

Mr. Wormald said the best composition he had been able to find for the purpose was shellac dissolved in methylated spirit. When dry it absolutely repelled the solution. His method of using it was to have dishes made of cedar, which, owing to its lightness, he preferred to any other wood. He warmed them, coated them well with solid paraffine until the wood had absorbed a considerable quantity, and then gave them two or three coats of shellac. He had followed that plan for some time, and found it very satisfactory.

Mr. Ratho inquired if Mr. Wormald had found the bath solution to have any effect upon the shellac. He thought the question remained in it must be a question of Mr. Balmer. Mr. Wormald had not found any deleterious effect arising from any such action. In his opinion the quantity was so small as to have no effect.

After some further desultory conversation, Mr. Bouzas asked if any member had had any experience in toning transparencies with platinum or iridium salts. He had experimented with them before and after fixing, each method giving very different results; but he had not been able to secure the fine brown tones seen in some of the commercial articles.

Mr. Ratho said the platinic chloride should be neutralised with carbonate of soda, as the presence of hydrochloric acid prevented the toning action.

No other subject being brought forward, it was decided, on the motion of Mr. Holgate, that the Society should hold its first out-door meeting, in Bolton Woods, on the 26th inst., and the meeting was adjourned.
Disputed Photographic Partnership: Whatey v. Monte—At the Bloomsbury County Court this case was heard before Mr. Judge Russell, on the 22nd inst., in which the plaintiff, described as a photographic business in High Street, Camden Town, sued the defendant, a photographer of Wood Green, to recover compensation for an alleged breach of contract, and for the value of some negatives and other articles detained by the defendant. Mr. Willis appeared for the plaintiff, Mr. Rylott for the defence. The plaintiff said in January, 1874, he was a tenant of the defendant’s, and owed him £88 arrears of rent, in consequence of which the defendant purchased various articles amounting to £21, and received from the plaintiff an IOU for £21, the balance due. The plaintiff further stated that with a view to set up in business for himself, the defendant offered that if he would bring his own connection, and devote his whole time to the business in High Street, he would take the plaintiff into partnership; and in consequence, on the 14th of January, 1875, he entered into this arrangement with the defendant. The defendant said under the name of Russell, he had, with the defendant’s consent, the names of Monte and Russell printed upon cards, and also had the receipts printed in their joint names. The plaintiff admitted, in cross-examination, that he never paid any of the local rates or taxes during the time he rented the premises from the defendant’s establishment. Miss Emily Taylor stated that she was employed by the defendant to receive customers, keep the books and cash, and her instructions were, after paying all trade expenses, to return to the plaintiff the balance of the receipts. Mr. Harris urged that as the plaintiff had failed to prove the existence of a partnership, there could be no case for compensation against the defendant. The defendant said that the plaintiff was formerly his tenant, but in consequence of his being in arrears of rent, offered to give the plaintiff’s goods together with the IOU, in satisfaction. Subsequently the plaintiff proposed to establish a number of portrait clubs, when it was agreed between both parties that the defendant should pay all the working expenses and divide the profits of the business. But the plaintiff’s speculation proved a failure, the arrangement could be terminated at once. The defendant said he was not aware of any cards or receipts being printed in their joint names till just before the plaintiff left, and that when he was dissatisfied with the defendant’s conduct he removed all the negatives and cleaning materials to his other establishment at Wood Green. The defendant further said his only object in entering into this arrangement with the plaintiff was that of rendering him some assistance, as the plaintiff was in need of assistance and out of work at the time. Miss Emily Taylor, being questioned, she had no idea of the existence of a partnership between the parties, and always looked to the defendant for her salary. Mr. Harris, having addressed the Court, the judge said he would reserve judgment for a week, and eventually gave judgment for defendant with costs.

Photography of the Electric Sparks—Mr. Leo Daft, photographer, of Troy, N.Y., a gentleman whose name seems familiar to us as at one time a photographer in this country, has sent the Scientific American several photo stereo scenes, recently made by electric discharges between the terminals of the static electrical machines. In some of the examples the picture shows the electrical flow divided into ten streams, which have the appearance of ten fine, white, zigzag wires, sharply defined, and arranged in the form of a elliptical framework. It is probable that the rays used in the terminals had something to do in giving the remarkable electric power to the sparks which these photo impressions indicate. Mr. Daft intends to continue his photo-electrical experiments, which are certainly very interesting.

A Photographer—Sergeant Verrall, of the East Sussex Constabulary, was charged before the Cockfield magistrates with assaulting Mr. Lombardi, photographer, at Brighton. Complainant, while returning home, was called into a house to assist in attending to a man who had been fallen down. The defendant was then in the house. On the opinion of several witnesses, he was the worse for liquor. Mr. Lombardi asked his number, which he refused, and an altercation followed, during which the alleged assault was committed. Verrall was fined 40s. and costs.

Diaphragm.—The position of the Waterhouse diaphragm between the front and back lenses of a portrait combination is determined by the fact that the front lens is seven-eighths of the total length of the said lenses, and the back lens is one-eighth of the total length of the said lenses; and so, whatever the focus of the lenses, in due relation. We do not know the lenses in your half-plate combination, but you must ascertain first, and then place the diaphragm so as to make the position of the objects more plain: suppose the front lens a focus of 10 inches, the back lens a focus of 15 inches, and the total separation 6 inches, the diaphragm must be placed 9 inches in front of the back lens, and 2 inches behind the front lens. This position gives the maximum of advantages. To secure extreme flatness of field you may place the stop nearer to the front lens.

H. W.—Your copying camera, with lens in the middle, and grooves for negative and dark slides at the ends, ought to have been provided with a means for uncovering the lens without opening the flap at the top. The simplest means is to place a hinged shutter behind the lens, which opens and shuts by means of a pinion at the side of the camera. The absence of this arrangement is doubtless an oversight in making. It will be easily added by a camera maker; or it would not be difficult to improvise if you were skilful in the use of tools.

H. Taylor.—An arrangement of curvatures such as you mention may be made to give pretty good effects of light and shade. Let the canopy overhead project at least six feet; the curtain on the shadowed side of the face about eight or ten feet; and that on the other side only a foot or two. Then, if you have some sliding arrangement which will permit you to adjust these so as to suit different sitters and different conditions of light, etc. We fear from your example and description that the lens is not a very good one; but the want of sharpness may arise from want of experience in focusing; or it may be from the ground glass and sensitive plate not being in exactly the same plane when in the camera. Do you get a sharp image on the ground glass? If you do not, and not in the negative, the fault may be remedied. But if you cannot get a sharp image on the ground glass, the fault is in the lens. Either C or D of the names you mention will be most likely to suit you. We shall at all times have pleasure in helping you.

K. E. C. B.—There is no international copyright law between England and America, and hence an American copyright is not protected in this country, nor an English copyright in America.

W. B.—You had better throw away your hypsophot, which is contaminated with iron. There is risk in using it. 2. On adding bicarbonate of Soda to a silver bath to neutralise it, carbonic acid is given off, and heaping with lime, an acid reaction is of course found to exist. After the solution has remained some time in an open vessel to allow the carbonic acid to escape, you will find the solution neutral. The simple test of sufficient of the carbonate being having been at all, there has been pressure, if a turbidity appears, it shows that all the free acid is neutralised, and that the soda salt is decomposing the nitrate of silver, and throwing down carbonate of silver. No more of the soda solution should be added after that.

An Amateur Reader.—In sensitising common paper with bichromate of potash you form a combination between the chromic salt and the size. This being by a considerable extent in the body of the paper, the picture of any opposite phenomena, the use of a mixture of gelatine or albumen with very short float on the chromatate solution affords the best hope of remedy; but we have never seen brilliant or rich prints obtained by the method you are trying.

Y. M. F.—We do not know of any objection to a one-grain solution of India-rubber as a preliminary coating in the wet process, except that it is somewhat more troublesome to deal with than albumen, the solvent being necessarily very volatile, and the process time-consuming, of course, as the white water experimental approached.

F. Hopkins.—There is not any general law so far as we are aware in relation to the show-rooms of photographers. A case like yours would be dealt with under the local laws of the place where the business is conducted. As our specimen.

L. Hill.—The address has been misprinted; but we will endeavour to find it and let you know.

Received.—"Ram Rhydes," by W. A. Chandler, Illustrated by Edwin Cocking.

PHOTOGRAPHY IN AND OUT OF THE STUDIO

THE RECENT GUNCOTTON EXPLOSION AT WOOLWICH.—THE ACTION OF HYDROGEN UPON NITRATE OF SILVER.—THE BREMEN PHOTOGRAPHIC SOCIETY.

The Recent Guncotton Explosion at Woolwich.—The disastrous accident with guncotton at Woolwich, last week, can scarcely be without interest to photographers, for, after its employment as a military and blasting agent, there is no greater application of the material than in photography, although the products used by photographers for the manufacture of their collodion are not precisely the same chemical compound as the very explosive material that engineers and miners deal with, still there is enough resemblance to cause them to be practically regarded as the same thing. It was only the other day that we recommended our readers to keep any large supplies of guncotton they might have in a moist state, adding twenty or thirty per cent. of water to it, for, if in damp condition pyroxetin is a comparatively harmless body. Not only will it refuse to explode under the same conditions as dry guncotton—that is to say, by means of a detonate fuse—but it is altogether uninflammable when a flame or red-hot iron is approached to it. According to the experience of chemists well versed in its properties, wet guncotton would be exploded only when a charge of material is in contact with it, and this is fired first of all. That no other way exists of detonating or exploding wet guncotton it is, perhaps, too much to say in the face of the explosion that has recently occurred; but, that photographers may not be alarmed in any way, we will detail the precise circumstances under which the charge of wet guncotton was actually exploded at Woolwich. Some experiments were being made at Shoeburyness with the object of testing the explosive properties of dry guncotton, and to carry these on a few shells filled with the explosive were required. When dry guncotton was put into shells and fired some years ago at Shoeburyness, the charge exploded, on the discharge of the gun, while yet the shell was inside the bore of the cannon, and the latter being badly injured, no further experiments were made. When, however, it was found that wet guncotton could be detonated under the conditions we have mentioned, such experiments were decided upon by shells filled with wet guncotton. It is, of course, the object of artillerymen to detonate a shell at the end of its flight into as many fragments as possible, and the violent manner in which guncotton detonates seemed to promise an effective way of doing so. The wet guncotton, it was found, did not explode on the discharge of the gun, so they determined to cram in as much cotton as the shell would hold, in order to shiver it into fragments. Wet guncotton has been considered to be such a harmless material that instead of being manipulated in a small shed far removed from human habitations, as is the case when gunpowder is handled, it has been worked in a factory where many scores of men and lads were engaged on other operations. Four men, who had been specially instructed to fill the shells employed a powerful hydraulic ram for pressing the material into the projectile, and in this way it was tightly filled. A space was required at the head of the shell to receive the charge of dry guncotton which was to start the detonation, and, to make room for this, a pointed metal plug was forced into the mass of cotton. At this moment the explosion occurred, the fragment of shell breaking into pieces lacerated two men so severely that they died soon afterwards, while a third was badly injured. The curious part of the business was this: although there was an explosion, only a small portion of charge was burnt, and the shell was broken up into very large fragments. Had there been a detonation, the whole mass of guncotton would have been consumed, and the shock been far more violent. Indeed, not only the factory, but buildings in the vicinity must have been levelled to the ground under such circumstances, and herein lies the cry. The solution of the matter would appear to be that heat was evolved by the hydraulic ram forced into the guncotton at a high pressure, so that a portion of the material around became dry, and the friction between the ram and the bottom of the iron shell (supposing the ram to have reached the bottom) set fire, and exploded so much of the cotton as would burn, and in this way the shell was burst in the mild form we have, seen. It was, upon one must admit, a very severe test for even the safest of explosions to bear, and really one can hardly be astonished that even wet guncotton should not become dangerous under such a trial. One cannot have to do with a dangerous material without running some sort of risk; but photographers, we repeat, need not be apprehensive in any way at the occurrence. There can be no doubt that to keep pyroxetin in a moist state is the best plan of insuring oneself against risk, and as photographers never have occasion to treat the material in any vigorous manner, similar to that we have described, there need be no fear of danger from its storage in this way. Under any circumstances, it is foolish to regard pyroxetin, or other similar compounds, in any other light than as dangerous explosives, and they should therefore always be treated with such. We are doubtless that the authorities of the Royal Arsenal will take measures to prevent the recurrence of such a lamentable affair.

The Action of Hydrogen Upon Nitrate of Silver.—It will be remembered that a short time ago we alluded to some experiments undertaken by Dr. Russell, whose results seemed to prove that pure hydrogen had a reducing action upon nitrate of silver. The experiments were made at Shoeburyness with the object of testing the explosive properties of dry guncotton, and to carry these on a few shells filled with the explosive were required. When dry guncotton was put into shells and fired some years ago at Shoeburyness, the charge exploded, on the discharge of the gun, while yet the shell was inside the bore of the cannon, and the latter being badly injured, no further experiments were made. When, however, it was found that wet guncotton could be detonated under the conditions we have mentioned, such experiments were decided upon by shells filled with wet guncotton. It is, of course, the object of artillerymen to detonate a shell at the end of its flight into as many fragments as possible, and the violent manner in which guncotton detonates seemed to promise an effective way of doing so. The wet guncotton, it was found, did not explode on the discharge of the gun, so they determined to cram in as much cotton as the shell would hold, in order to shiver it into fragments. Wet guncotton has been considered to be such a harmless material that instead of being manipulated in a small shed far removed from human habitations, as is the case when gunpowder is handled, it has been worked in a factory where many scores of men and lads were engaged on other operations. Four men, who had been specially instructed to fill the shells employed a powerful hydraulic ram for pressing the material into the projectile, and in this way it was tightly filled. A space was required at the head of the shell to receive the charge of dry guncotton which was to start the detonation, and, to make room for this, a pointed metal plug was forced into the mass of cotton. At this moment the explosion occurred, the fragment of shell breaking into pieces lacerated two men so severely that they died soon afterwards, while a third was badly injured. The curious part of the business was this: although there was an explosion, only a small portion of charge was burnt, and the shell was broken up into very large fragments. Had there been a detonation, the whole mass of guncotton would have been consumed, and the shock been far more violent. Indeed, not only the factory, but buildings in the vicinity must have been levelled to

THE BREMEN PHOTOGRAPHIC SOCIETY.—A photographic society has just been established at Bremen which already numbers thirty members. Hamburg, a sister seaport town in the north, has for a long time past had its society; but these two are the only second-rate towns of Germany which have such bodies. Berlin till very lately had two societies, but one of them, we believe, now extinct; at any rate, its organ, Licht, has for some time past failed to appear. Since Dr. Krone, the president of the Dresden Photographic Society and editor of Helios, went off to the South Pacific to observe the transit of Venus, we have had no photographic news from that nautical capital. The recent Vienna and Berlin have been the only two cities where photographers have met together. We trust that the formation of the Bremen Society is a good omen, and that other large cities in Germany will also follow suit in the revival or organization of photographic societies.

THE PRACTICAL PRINTER IN AMERICA.

ROLLING THE PRINTS.

The prints, after they are properly "spotted," are ready to be rolled, which should be done at the time when they
are slightly damp, as a better polish is then given to them. There are a number of presses in use which are generally good. A nickel plating is given to many presses, because it prevents their rusting. There are, of course, a number of different size presses for large and small prints. The common cartes and imperial prints should never be rolled on a table. The press should be thoroughly cleaned with a piece of cotton-flannel, and a little common alcohol. When not in use, always keep the presses covered. About once a week they should be thoroughly cleaned, and oiled with a drop or two of sweet oil. When the press is cleaned the prints are, one at a time, to be placed in between the rollers, either face up or face down, according to which roller is the polishier. They should be placed in with the left hand, while the right hand turns the crank. The pressure at the press should not be so heavy that the operator at it will experience any difficulty whatever in turning the crank with one hand, while the press is fed with the other. Do not stop turning the crank while a print is between the rollers, or it will be creased, and consequently ruined. Roll the print carefully, with a decided pressure, the lengthwise, and then twice sideways, and then roll the card only once. Then turn the crank, the pressure being on the print, and place the card on the other side of the press where it comes out; take hold of the card when it appears, and bend it so that the back will bend in slightly, and thus give the picture the look of being pressed forward. Bend in the back of the card, but a very little, however.

Mr. Bearn recommends the judicious use of Entrain's Oscillating Enameller, an instrument which gives a similar result, by somewhat similar means, to that produced by Weston's Burnisher. He says: "It is good for several reasons, among which are the following:— 1st. It decidedly improves the tone of the print. 2nd. It makes the general appearance of the print richer. 3rd. It gives transparency and bearing the whole print, especially in the shadows."

The prints, after they are rolled, are ready to receive the final treatment, which ends the processes through which they have to go before delivery.

**Waxing of the Prints.**

For the purpose of finding the best thing for waxing the prints, I have, at the expense of considerable time, experimented, and I have, I think, succeeded in finding what I was after; and although it is not new, yet I can recommend it to be the best, of more than a score of kinds of pastes that I have made, mainly on account of its cheapness and simplicity in the making.

Boiling water is generally used in the making of this paste, and for those who may wish a formula containing it, the one below will be found to be excellent.

- Virgin white wax... ... 2 ounces
- White Marseilles soap... ... 1½
- Boiling water... ... 2

Cut both the wax and soap into very thin slices, and place in a clean china mug containing the boiling water, and place the mug with its contents into a tin pan, also containing boiling water, the whole of which is placed on a hot stove. Add the wax and soap, a portion at a time, until all are dissolved.

I recommend the dissolving of the soap and wax in small quantities, as it will be more thoroughly done. In obtaining Marseilles soap, always procure the white, and never the spotted. While the wax and soap are dissolving, stir thoroughly with a clean glass rod. This paste, when made, will have the consistency of "cosmoline." When cooled, it is ready for use, and should be applied as will be given below. A few drops either of the essence of lavender, cloves, citronella, rosemary, bergamot, &c., may be added to give an agreeable perfume to the paste.

The above formula containing benzole, oil of spike, gum elemi, &c., in various proportions, which ingredients being a little difficult to obtain and to prepare, it is a matter of considerable trouble to the beginner, consequently I will not place them here.

Out of all of the different kinds of paste I have made I have settled down to that of plain wax and spirits of turpentine. It is made as follows: white wax is placed, in a common clean china mug; which mug is placed, as above described, in a pan containing water, which is kept at a boiling state by being placed over the gas stove. Dissolve about two or three ounces of the wax in the mug, and then gradually add about t-four quarts as much spirits of turpentine as there is dissolved wax, stirring well all of the time, and finally add of some essence—as the essence of bergamot—in quantity sufficient to destroy the small of the spirits (said quantity being about half an ounce). Stir the whole thing well.

So that a quantity of photographs can be waxed in a comparatively short time, I made a couple of wooden frames (see fig.), one for the small carte, and another for the imperial. They are very simple in construction, being merely a suitable-size piece of placed pined wood (upon which the back of the card rests while waxing), with narrow strips of wood nailed on the top, bottom, and one side of them, The prints are placed in those frames for the purpose of keeping them from slipping about. Instead of having the strips A A A fastened to the main board, as it is in the fig. they (the strips) can be movable, and fastened to the print when necessary by means of a thumb-screw.

By the aid of these frames I have thoroughly waxed one hundred carte-de-visite photographs in an hour and a quarter.

This paste should be applied to the prints by placing a small quantity on the hardest (i.e., the unopened) side of some Canton flannel and rubbing it well over every part of the print, and then, with another and a cleaner piece of flannel, the surface of the print is rubbed briskly until quite dry, and then the final polish is given by using the soft (napped) side of the same piece.

I have recommended to use the harder side of the flannel first, because if the other is used before the greater part of the wax is rubbed dry it will remove the stringy cotton stuff, and thus it would be rubbed in the wax on the surface of the print, which will, especially when looked at obliquely, show very badly. Rubbing quickly will give a most marvellous polish to the print, especially if it has previously been cleaned, and assists wonderfully in bringing out detail in the deep shadows, and also gives a fine effect to the whole print.

Soiled photographs are rendered so clean by the use of this paste that they will look like fresh ones.

The prints, when waxed, should be allowed to remain all night, or at least for a few hours, in a cool and thoroughly clean room.

---

**PRACTICAL PORTRAIT PHOTOGRAPHY.**

BY WILLIAM HEIGHWAY.

**CHAPTER VI.**

**THE MANIPULATIONS IN THE DARK ROOM.**

**Coating the Plate with Collodion.**—So many descriptions have been written of this operation, most of which seem to paraphrase Hamlet's instruction of Rosencrantz and Guildenstern in the art of playing on the pipe, that I am almost tempted to tell the reader to see it done by some experienced operator, for that is almost necessary. Practice alone will enable you to coat a plate with a perfectly clean and even film. The plate is held, resting on the edge of the first finger and middle joint of the second finger, with the face of the plate, and the tip of the thumb over, as seen in the diagram. It would be well to practice holding the plate in this position firmly yet gently, before prac-
the fore-finger into the centre of the under side of the plate, and the thumb over the corner, the result being that the warmth communicated by the tips of the fingers to the plate causes the collodion to set, on those points too rapidly, and thereby spoil the negative, as the thumb has done its share of mischief by coming in contact with the collodion, causing stains and breakage of the film.

Hold the surface perfectly horizontal when pouring on the collodion at point A, and continue till the collodion has reached the outer edge of the plate, then direct it by gently tilting it to B, then by lowering the level of the corner at C it will flow there, and letting it escape the tip of the thumb flow it to D corner, under which you should have the collodion bottle ready to catch the surplus. Without *very much* alteration of the horizontal position of the plate, it should be very gently rocked until its film is set; i.e., when on touching its surface with the finger it receives an impression of it as in soft wax without tearing away. It is now ready to be immersed in the bath. It is very necessary to succeed that while enough collodion is poured on the plate, it shall not receive too much. Experience alone can enable you to determine this.

The Immersion of the Collodionised Plate into the Silver Bath. —This operation is also a peculiar one, requiring care and steadiness. The plate is placed on the dip rod in the direction held in the previous manipulation, the edge B A resting on the edge of the “set” film that one edge—that which the collodion first covered (which we will call the upper edge)—is thinner than that which it last reached, and was lowest when the surplus was drained off. Of consequence, the upper edge sets a little quicker than the lower, and is one of the reasons why it is immersed first. The plate, properly resting on the dipper, is gently lowered, steadily and without hesitation, into the silver solution, and immediately it is submerged it is subjected to a gentle motion by a circular movement of the hand. When first immersed the alcohol and ether in the collodion film repels the water of the bath, and if the plate were now viewed it would be seen to have what is technically known as a “greasy” appearance, similar to a greasy plate on which water has been poured. The nearer solution first clings to the plate in drops and patches, then in little rivers and streaks, and finally the whole of the collodion film becomes smooth and creamy; after this point is reached allow the plate to remain in the bath a minute.

If the plate has been immersed too soon after coating with collodion, before it is properly set, the water in the bath precipitates the copper of the collodion, and gives rise to a spotty appearance on the plate. If, on the contrary, the plate has been held too long before putting it into the bath, the uneven evaporation of the collodion causes bluish patches in the film, which are insensitive to the action of light. Too rapid an immersion causes streaks, and a plate arrested in its descent will be marked with a horizontal line indicating the surface of the bath solution at the moment of stoppage; these are known as “hesitation lines.” When the plate is removed too soon, although it may have a smooth surface, the required solution has not flowed out, causing streaks by inequality of sensitiveness, which streaks become painfully manifest on development of the plate. Being perfectly satisfied that the plate is sufficiently sensitized, it is held up on the edge of the bath to drain for a few moments, and then placed in the carrier or holder. This should be done as the plate was before placed on the dipper, the thin edge downwards, because the flow of the water in draining the plate has been that way, and to reverse it would cause a reflow of the silver over the surface of the plate, thereby causing streaks, and because after exposure, the plate is taken out and held by the now upper and thick edge, that being the best to develop from, for reasons which will be explained when we come to consider the development of the plate. The film at the time of placing the plate in the holder should be perfectly smooth and of creamy semi-transparency, not at all bluish in colour. After exposure in the camera, to which it is taken when the shutter of the holder is closed, it will be found to have gained in density, i.e., become more opaque, retaining its creamy colour, showing conclusively that decomposition has been going on after its withdrawal from the bath. The plate should not be prepared any considerable time before it is required for exposure, otherwise insensitive patches mark the places where the film has dried, and metallic silver stains where the solution on the surface has been drawn from the lower edge (as in the carrier by capillary attraction). Improperly carrying the carrier or holder in a horizontal position causes the same markings, by allowing the silver solution to run over the plate.

Nothing definite can be said relative to the length of exposure, as that is entirely dependent on the amount of light and the nature of the subject, the state of the atmosphere and the time of day, &c. This subject will be treated more fully when we are under the skylight, and we may presume that having done our part in the dark room, the plate has been handed to the skylight operator, and that it is properly timed in the exposure.

We now approach the most delicate and beautiful of the manipulations of the dark room—developing. Before we say anything on this subject one or two remarks in warning are necessary, which will be the duty of the carrier. It must be held or stood in perpendicular or upright position from the time of the plate being placed in until it is taken out. It should not be kept a long time waiting for the arrangement of the sitter, as that should be done before the plate is withdrawn from the bath. Two pictures should not be made on one plate, unless they are two of the same sitter in the same position with the same light and exposure, or unequal results will be the consequence, as will be seen when we understand the development. It is impossible to get identically the same conditions in a plate at different times, because the character of the plate is undergoing a continuous change; nor can you get the same conditions of light and exposure. Keep the carrier clean. After each plate, wipe it out with a cloth or piece of cotton, or piece of blotting-paper, or in dusty, as, on its withdrawal to make the exposure, the dust is set in motion to the detriment of the plate. Preserve the carrier from splashes of any of the solutions. Silver is a great enemy to the existence of the carrier, and to guard against some measure against its action on the wood and corners it should be frequently rubbed over on the inside. This, too, attracts and holds any stray particles of dust (which are sure to be set in motion by the withdrawal of the slide), as well as protecting your finger from the action of the silver from the plate. Place one or two thicknesses of blotting-paper on the back of the plate in the carrier, as this prevents a great deal of silver from running down.
NORTH LIGHT FOR STUDIOS.

Mr. S. V. Allen, in our Chicago contemporary, the Western Photographic News, in the course of a series of articles on "Popular Photographic Blunders," attacks the common prejudice in favour of a pure northern light. He says:

"The respondent with scorn the offer of any other than a pure northern light. Perhaps it would be more exact to say he repels the suggestion with contemptuous indifference. The merest tyro, as well as the practised operator, is equally settled in his convictions on this point. With nineteen out of every twenty photographers, the vast majority of a northern light for any and every other light is a point that is absolutely settled—settled beyond the remotest possible necessity of discussion. The suggestion that all this may possibly be wrong, and that further consideration might well be given the subject, is a photographic heresy so rank, and indicates so plainly the mere breakeen, that it does not even provoke irritation. It does provoke pity, and it may beget contempt for your chimerical notions. So much I know will presage the ultimate extinction of the books advocating north lights, as though no other lights could by any possibility compete with them. In fact, the books ignore everything except a north light; or if, by chance, an east or west light is mentioned at all, it is with expressions of sympathy or commiseration for the unhappy proprietor. But if a west or an east light is mentioned at all, it is a sop of the north-light builder, what shall be thought of the one who deliberately and of choice expends money on a south light? The silence of our favourite writers on this subject is significant—be it evidently beneath compassion. The enormity of his blunder protects him even from ridicule.

"Now, if we could always secure a 'pure northern light' in constructing our ateliers, this subject might not be a very important one. But it is often more convenient to obtain a south sky and side light. Hence the vast importance of knowing the relative values of different lights.

"First let me say that I regard this exaggerated prejudice against 'southern lights' as one of the most surprising photographic blunders. I am often astonished at the great number of persons who have the idea, as I am not, that a north light is of more use than a south light. But there are a few of which I must speak in this article.

"Especially dear to the heart of the photographer, and believed in with all the irrational taste of unreasoning superstition, is the theory that a north side and skylight is superlatively stable, unchanging, reliable, and not given to perplexing changes as all other lights are. Our books are full of this notion; our ideas are saturated with it. It is a theory so well fixed in our minds that we never reason on it. But in reality no notion could be more erroneous, no theory more false. In the whole circuit of the heavens be selective of the skylight that is more subject to perplexing changes and to absolute variations of the light. In this matter I am trying to be practical. I am referring to ateliers as they exist—to the ninety and nine out of every hundred, and not to the mythical atelier with a 'pure, steady, unchanging, unobstructed northern light,' which, strangely enough, we all think so common, but which in reality has an existence, except in the unfeigned pliability of our imaginations, and which, further, I firmly believe to be practically an impossibility.

"I would particularly wish it understood that when, in this connection, I speak of a 'steady, unchanging' light, I do not refer to the changes in the amount of light, for a skylight in any direction whatever will be subject to such changes. I refer only to what is of vastly greater importance, viz., the changes in the direction of the light.

"To give greater perspicuity to this division of the subject, I will use the term north top window, instead of northern light, and for further convenience, let us suppose all northern windows divided into two classes, the first class being entirely protected by some means (such as high buildings, shutters, screens, walls, &c.) from the rays of the sun throughout the year, the second class not being so protected. The first class, of which there is, perhaps, one gallery in a hundred, is easily disposed of; for there is, even with the best arrangement, a certain loss of at least one-fourth of all the light that should fall upon the top window. This may be thought a wild statement; careful observation will prove that it is a true one.

"But how is it with the second class? As a rule the sun's rays, especially in summer, strike first in the morning upon the north-east corner of the top window, gradually changing towards noon to the north half (or to the whole, according to the pitch and other obstructions), thence in the afternoon gradually changing to the north-west corner, and finally in summer shining more or less fully and squarely upon the whole top window. Thus it will be seen that with most galleries the light, even on a clear day, is not the same for five minutes at a time. It is quite impossible to arrange the screens, curtains, and reflectors, and without changing them, make two negatives that are identical in the light. (It may be seen from this, by the way, how thoroughly absurd it is to talk in terms of artistic blunder, of supposing that the art of lighting can ever be taught through books, by showing which curtains should be opened and which closed, for absolutely different results would be obtained at nearly every sitting.) To illustrate this, let us suppose a sitter placed at any point under a top window, say under the centre. In the morning the light is uniformly dull from the whole top, a little later a strongly concentrated light comes from the north-east corner, later still a broadside from the whole north half, then from the north-west, and finally, later in the day, a flood of bright light from the whole top. Of course, as I have said, this will not be the exact order of variation for every north top window, but it fairly represents the variability of all of which I have enumerated class two, which means nineteen of all the ateliers in the country.

"Not only is the direction of the light constantly changing from morning to evening, but even its changes are not the same from day to day. As the path of the sun varies with the time of the year, from a nearly horizontal direction in winter to a nearly vertical direction in mid-summer, so do the changes of the light vary—a fact which alone is a very serious inconvenience, for on only two days in the year, the sun follows the path of the sun of the opposite.

"Now add to all these sources of uncertainty the fact that on all days on which there are floating clouds in the sky the direction of the principal light is subject to absolute, absolute, and momentary changes (from bright clouds reflecting the sun's rays at every possible and 'unexpected angle'), and you have my principal reasons for exposing myself to the censure of my photographic friends on the question of the north window. A north window is nothing more than a more perplexing and changeable of all lights. Except for the truths contained in these assertions, it would be quite impossible to account for the enthusiastic and absurd effects of lighting so frequently produced in first-class galleries by competent artists; and it also accounts for the exquisitely beautiful effect of light which we occasionally see produced in miscue, to produce the effect by means of which we understand even the first principles of correct lighting. They are produced by chance. The skilful operator poses his subject, places his camera, draws his curtains, adjusts his eye-rest, sets his reflectors, animates his model: the effect is just to his liking. One minute passes, and he is ready to expose. But now the lighting does not suit him quite as well as before. Why? The sun has changed its position very slightly; the light is changed—only slightly, but the effect is more tame—just a portion of the
delicate brilliancy is gone. But time presses, and the exposure is to be made; in fact, it must be made, and it must be made that very instant, otherwise the sitter becomes nervous, and the expression listless. There is not one second of time to fool away after the focus is drawn and the model is ready. The skilful operator knows all this intuitively, so the exposure is made and the plate is done in a burst. But for all that, he must precisely when he aims to produce, only in the moment of exposure. He has no time to stop and say, 'This is a good negative, but it lacks a little brilliancy he hoped to secure, and would have secured if the lighting had not changed. Another sitting is made; the same careful adjustment of accessories; the same beautiful image is seen on the ground glass; the plate is ready; five seconds gone; your lens is uncovered. But he is not satisfied, and you have not anything so sensitive as paper, or of that 'hope deferred which maketh the heart sick,' when they develop their negatives. With such artists, really intelligent operators have little sympathy. It is worthy of note, however, that these self-satisfied gentlemen always make their pipes of contentment where specimens of their ignorance of the laws of lighting are to be found in abundance. They cannot comprehend that delicacy and precision in lighting are truth and harmony in representation. Like Plate, they may ask feebly, 'What is truth?' but, like him also, they are indifferent about the answer.

This, however, is a digression. I have endeavoured to point out as clearly as possible, an imperfection in our means of lighting that is a constant source of annoyance and embarrassment, and a frequent source of failure to every operator who aims to produce fine pictures. I think every competent operator will, on careful thought, agree with me that fully one-fourth of the failures in lighting may be ascribed to the causes I have mentioned. The question is, I suppose, that of the means of getting rid of the difficulty. Is there any possible way of securing in reality what we all so sincerely believe we already possess? — i.e., an unobstructed light that is constant in its direction, and not subject to the varying changes that have been described? Theoretically it is quite impossible; but for all practical purposes there is a solution to the difficulty."

**FORMATE OF IRON AS A DEVELOPING AGENT:**

**BY S. BOTTOMS.**

When I first took up the study of photography, in 1854, my kind friend, Mr. H. Deane, called my attention to the peculiar effect of formic acid in changing the tone of the metallic deposit, when employed in conjunction with sulphate of iron in the developer. In those days negatives were developed either entirely with a weak iron developer, or with pyrogallic acid alone; the successive application of the two being undesired. I was considered a very successful positive operator, and naturally turned all my attention to that particular branch of the collodion process. The great aim of those who produced glass positives was to procure as white a deposit as possible, so as to insure plenty of contrast. A recipe in which formic acid formed an essential feature, and which gave rather peculiar results, was as follows — Sulphate of iron, 60 grms.; water, 4 ovs.; alcohol, 1 dram; formic acid, 1 dram; acetic acid, 1 dram; formic acid, 30

**ACTION OF DIFFERENTLY REFRAangible RAYS ON IOIDE AND BROMIDE OF SILVER.**

BY E. BECQUEREL.

When a sensitive photographic plate, prepared in the ordinary manner with iron solution and collodion, is exposed for a short time to the solar spectrum, the image, when developed with pyrogallic acid, is found to extend only from the violet to between F and G. But if a little chlorophyll is added to the collodion employed, the plate, under the same conditions, shows also a feeble but well-defined action, extending from E to beyond B in the red, with a remarkable and strongly marked band of maximum intensity between C and D. The yellow and red bands of this band, however, is much weaker than that which takes place in the violet, and attains the intensity of the latter only when the red end is exposed from five to ten times as long as the violet. Other much less strongly marked bands may be perceived between E and B. The author finds that the conspicuous band between C and D coincides in position with the characteristic absorption-band of chlorophyll, as he observed it in the collodion solutions made use of in preparing the plates. The colouring matter on the photographic plates obviously does not act as a screen, cutting off the absorbed rays, for in that case the contrary effect would be produced; but we may explain the phenomenon by supposing that the silver salt is so connected with the chlorophyll that an action set up in the latter by the rays it absorbs communicates an impulse to the former by virtue of the intimate association of their particles.

The author long ago showed that when sensitive plates are exposed for an instant to sunlight before submitting them to the spectrum, the range of the chemical action is greatly extended towards the less refrangible end. These earlier observations are readily explained by the results above described. We may suppose the exposure to operate by producing a change of colour, or other physical condition of the upper film of the plate, by which its absorptive power for the different rays is altered.
"NONPAREIL" OR "ALBA" PLATES FOR PHOTOGRAPHS.

We called the attention of our readers to an American novelty in the shape of a white enamelled iron plate as a substitute for opal glass in photography, announced as "Nonpareil" plates and "Alba" plates, both being, we believe, precisely the same thing, the different names indicating different agencies rather than different manufacture. We are now indebted to the courtesy of Messrs. Anthony and Co. for an example of the Nonpareil picture, and to the courtesy of Mr. Atkinson, of Manchester, for examples of the plates, and of the collodio-chloride of silver with which they work. Anthony and Co. for working with these plates. A few words of description of the materials and results will probably interest our readers.

The Nonpareil plates seem to be in every way a singularly excellent basis for a photographic portrait. Thin, light, and sufficiently rigid, like the ordinary ferrotype plate, the Nonpareil, instead of black or chocolate, like the ferrotype, presents a fine delicate matt surface of pure white, surpassing almost any similar surface we know, but most like the surface of pure white marble, smoothest, but not polished. Whilst perfectly rigid and free from liability to warp, cockle, or readily bend, break, or injure in any way, it is as light as a piece of card, and may be cut with scissors in a similar manner; hence for lobbies and similar matters it affords singular convenience. The Nonpareil picture sent from New York is printed by the collodio-chloride process; and is in every way charming. We at once put the collodio-chloride sent by Mr. Atkinson and the plates to the test of practice. The plates do not require preliminary coating or preparation of any kind, but are sold ready for use. The collodio-chloride prepared by Messrs. Anthony and Co. is sent out in two bottles, one containing colloidion with nitrate of silver in solution, and the other a mixture of sodium chloride in solution. The two require mixing in equal parts in accordance with accompanying instructions, and the mixture, after standing for a short time (say a quarter of an hour), is ready for use. The plate is coated in the ordinary way, and allowed to dry in the dark. It is scarcely necessary to remark that care should be used to see that the coating is thin, and where it is too thick it should be quite dry, so as to avoid injury to the negative in contact printing. In the instructions forwarded with the collodio-chloride, fuming the film is recommended, and we have no doubt, from experience, that greater sensitiveness and greater richness would be the result; but we proceeded to print without the fuming, and obtained perfectly satisfactory results. The exposure in printing was much shorter than would have been necessary with ordinary albumenized paper, and the colour a rich warm purple, bronzing readily in the deep shadows. We tried toning with a bath of sulphocyanide of gold, similar to that which we have described as working well with collodio-chloride prints on paper, which answered admirably. We also tried an improvised bath, made by adding a little chalk to a concentrated solution of chloride, then pouring in water cold. In this case we made the bath very weak, about fifteen ounces of water being used to one grain of chloride of gold. This toning bath also answered perfectly. In fact, any of the usual toning baths, employed somewhat weak, will, we doubt not, give good results. The fixing and washing are very rapidly effected, involving neither the time, labour, nor certainty involved in washing prints in the ordinary silver printing process.

The operations in producing the Nonpareil photograph are as simple as the results are pleasing. In working with collodio-chloride on opal glass, considerable care is at all times necessary to avoid injury to the surface of print or negative from the pressure of two unyielding surfaces, and equal care to avoid the breakage of the glass. There is also necessary in working with a movable frame to secure exact register in examining the progress of the work. With these plates such care and anxiety become unnecessary. Whilst the plates possess sufficient rigidity for every purpose required, being very thin, they are not absolutely unyielding, and therefore there is no risk of breakage or abrasion of the surface. Being elastic, the progress of printing may be examined as in paper prints, rendering no special pressure frame necessary. In short, this plate seems to supply both in beauty and convenience the very tablets for which we often wished in prosecuting our experiments in working out the collodio-chloride process before presenting it to the public. It is easy and simple to use, and the results are charming; and we think there can be but little doubt of the advantage of the method.

We should add that whilst the Nonpareil plates are especially designed for collodio-chloride printing, they appear to be available for various other purposes. They may be used for developed collodion prints produced in the camera by the wet process, for transferred collodion films, and as a basis for carbon prints, and, in fact, any purpose where a very pure white surface is required on a support almost indestructible.

WOODWARD'S MICRO-PHOTOGRAPHS.

The Photographic Society of Vienna has been favoured with a collection of pictures from Lieutenant-Colonel Woodward, of Washington, produced by means of a microscopic lens. Colonel Woodward, it appears, has experimented with all sorts of lights in the production of photographs of microscopic objects, and has used for the purpose sunlight, electric light, lime light, and magnesium light. He does not work with the aid of a camera, but in a darkened room, so that between the lens and the dark glass there is a free space, and the focussing in this way is more easily effected.

Colonel Woodward prefers sunlight to any other, now that he has been able by means of a particular kind of illuminating apparatus or condenser to modify the sunlight, so that it gives results similar to the lime and electric light, which in the first instance gave the best results. Colonel Woodward is also using sunlight for his purpose, as in cloudless Washington, where clear skies are frequent, it is the cheapest mode of illumination; but he has made much use of magnesium light also, and has devised a peculiar arrangement for subduing the disagreeable magnesium vapours. He provides the short chimney of the box, in which the magnes-ium is burnt, with a spiral of wire, and round this is placed some coarse net, the end of the spiral or tube ter-
minating in a wide bag. The air goes through the netting whilst the cooled oxide of magnesium is collected in the interior of the pipe or in the bag.

Woodward employs various lenses for the production of his photographs; in the case of very large amplifications, immersion lenses are employed. His enlargements embrace the scale of a 400 diameters, and has been expanded with the Sanitary Division of the United States Army, and his main efforts in micro-photography are directed to the production of physiological preparations. The establishment to which he is attached possesses already thousands of negatives, and Colonel Woodward has forwarded to the Vienna Society a series of "test objects," which are, of course, exceedingly interesting. The Nobert Scota and Pleurosigma angularis and foraminas he has produced in different degrees of enlargement, illuminated by direct and also diagonal lighting. The pictures are exceedingly fine, and give a wonderful idea of the construction of the diatomacca. Of course, in the case of very extensive enlargements, the pictures are not very sharp, but the lines and drawing are remarkably clear, and not only are seen on the thousand negative, but some distinct detail is shown, and they are not merely rendered by three distinct lines; even the six-angled cells are visible in the pictures.

The Woodward photographs, being for the most part of a physiological nature, will be exceedingly useful for medical schools and museums. The employment of microscopic tube in this line of work would be obviated to some extent by micro-photographic illustrations, and these thrown upon a screen in class-rooms and lecture theatres, by means of artificial light, would be a material aid to professors. We know that many of the medical staff of our hospitals in London would consider themselves very fortunate to secure such photographs as Colonel Woodward has produced, and their publication to the public, and we are not only of the opinion would be a boon to many scientific men.

FRENCH CORRESPONDENCE.

METHOD OF OPERATING BY REFLECTION—HOW TO PRODUCE ORNAMENTAL BORDERS TO PORTRAITS—BLUE GLASS LENSES—DAY PLATES—A REGISTERING PHOTOMETER—M. LAMBERT IN ENGLAND—SPIRIT PHOTOGRAPHERS AND THE POLICE: A CUPBOARD FULL OF SPIRITS DISCOVERED.

Some days ago I received from a photographer who is already well known as having prepared a new kind of pyroline (M. Tassan, of Montauban) a letter describing a series of ingenious processes.

The first permitted him to utilise any space or apartment situated on the ground floor, and therefore but inadequately lighted, for carrying on photographic operations, being able to produce portraits as easily as in any glass studio. M. Tassan places the model about a metre from the illuminating opening or window; behind the model he places a portable background about a metre broad, and in front he fixes a mirror. It is the image reflected by the mirror that he photographs, and not the sitter. He asserts that by this means he can obtain all the effects of the light, including the lighting up of the face.

In the manner following he transforms old clichés, varnished or unvarnished, into pellicle images. He pours upon the negatives, placed horizontally, a film of special collodion, which he allows to dry. The cliché is in this way covered, as it were, with varnish, and is in a position to resist the printing of any number of copies. When it is desired to detach the film of collodion and negative image from the glass plate, the whole is plunged into a bath of water, and after three or four hours' immersion the whole image comes away with the greatest ease, and as it preserves its suppleness and flatness, it can be easily kept in good condition. I have had now in my possession, for some weeks, several clichés of this kind, and they are as perfect and as flat as on the first day. The author of this publication has also sent me some pictures of medallion format, with an ornamental border or framework which is obtained at one single printing by the aid of two clichés superposed. The first is an oval portrait in the middle of a plate which has been kept transparent at the margin during its sojourn in the camera, and the second cliché is executed from a bas-relief, the central portion (corresponding to the oval portrait) of the sensitive plate being protected by a mask from the action of light. The photographic apparatus is placed at a convenient distance, to reduce the image of the bas-relief to the proper dimensions of the plate. When the second negative has been obtained with a clear oval in the centre, the film is slipped on the way, and superposed on the first negative, so that the two may then be printed together. The same ornamental margin negative will of course serve for any number of portrait negatives.

The different processes of M. Tassan are ingenious, and the results which they furnish plead in their favour.

I spoke in a recent letter of the lenses of coloured glass which M. Berthiot has introduced into the middle of the instruments for increasing their rapidity, or, at least, to render the pictures they furnish more harmonious. M. Boivin has communicated to me a more simple means still, and quite as efficient, which he employs for the same purpose. It consists in placing about two millimetres in front of the sensitive plate (in the dark-slide) a plate of glass more or less tinted with blue, according to the effect it is intended to produce.

The dry collodion process is, in conjunction with carbon printing, the subject which just now occupies photographers most. The experiments made in this direction tend above all to augment the rapidity of the process, and I am very much mistaken if M. Francck de Villecholle has not solved the problem. I assisted, the other day, in his studio, at an apparatus which appears to me to be capable of considerable character. A plate prepared by him nearly a month previously was placed in a stereoscopic camera, and a view of the surrounding houses was obtained. One of the lenses was uncovered for ten seconds, giving one half of the plate this period of exposure; the other halt had but six seconds' exposure, through the second lens, and then the two pictures were developed at one and the same time, being, of course, upon the same plate. It was found that the first six seconds was ample. The development, which was very rapid, was conducted in the most simple manner. In the first place, alcohol and water, in equal parts, was poured upon the impressioned film, and then a mixture in equal parts of an alkaline solution and of pyrogallic acid. M. Francck has not yet given us the formula, nor the composition of his collodion; he has only affirmed that the whole of the improvement in the process consists in certain modifications of the old tannin process. Under the action of the alkaline developer the image appears immediately in all its details; without trying to develop it too much, it is intensified with silver, and in a few seconds assumes the requisite amount of vigour. M. Francck has assured us that with a portrait lens, and operating in a glass studio, it is easy to obtain, in a second very satisfactorily; and this is easy of belief after having seen the results.

M. Lucbert is constructing just now a registering photometer after an idea of M. Lambert. This very ingenious apparatus—which we will describe more fully as soon as the necessary drawings can be secured—possesses the advantage of advising the operator when the pose is sufficient. The photometer may be regulated according to the weather, just in the same way as a clock alarm may be set according to the hour you desire to be awakened. The same idea has been already worked upon by M. Boivin, who showed some time ago a bell photometer; but M. Lambert, it appears, has been the first to patent the invention.

Since I have mentioned M. Lambert's name, I may say how pleased I am to hear of his departure for England.
am sure that he will be graciously received in a country of progress like yours, for he is a man of intelligent activity, who has succeeded, despite the trammels of routine, to bring out upon a practical footing a process of enlarging and printing in carbon, which has for a long time past been considered by many to be attended by insurmountable obstacles. I am quite certain that when English photographers have seen his invention, Lambert-type, at work, they will at once understand the success that has attended his efforts in France, and they will find that nothing exaggerated has been said about the fine pictures produced in this style.

Last year I entertained the readers of the Photographic News with an account of the stir that was being made in Paris by fantastic portraits executed by a so-called spirit photographer. Notwithstanding some severe strictures in the public press upon this enterprise, it seems that a very large trade has been done in these wares for a long time past. So gigantic has the affair become of late, that the police have stepped in and put a stop to speculations which rested upon the credulity of purchasers. As I announced some weeks ago, the Prefecture of the Police has now a studio of its own, and thus it is enabled to appreciate and understand very readily any photographic matter that comes under its attention. One day a number of photographers accompanied by one of the photographic staff, presented themselves, therefore, one morning at the studio of the spirit photographer, and these customers desired that their portraits might be taken accompanied by a spectre. The artist posed one of them, focused and then, under the pretense of invoking a spirit, he asked his visitor to withdraw and to stop for a while into the waiting-room. After an absence of ten minutes the photographer called them back again, and begged the model to take his place once more. Instead of doing so, however, the Commissary of Police produced his badge of office, and introducing himself and his friend under their real titles, called upon the medium to acknowledge his trickery. It was no good refusing under these circumstances, and the operator, withdrawing his dark slide and to stop for a while into the waiting-room, which was a very weak image, which had been impressed upon the plate during their absence, of a little figure made up like a ghost. If the operator had not been arrested in time, a portrait would have been produced besides the ghostly figure, and a spirit photograph would have been the result. In an adjacent room I found quite a collection of draped dolls more or less like great men that have departed this life, which were used as occasion served. Quite a store cupboard full of spirits was discovered.

At this moment, the ingenious but misguided photographer in question is under orders to present himself before the Paris tribunal to answer to a charge of swindling the public.

A GRATIFYING ACKNOWLEDGMENT.

BY W. T. BOVEY.

The many, among photographers, whose minds have long been painfully exercised because of the humiliating status ceded them by a non-discerning public, cannot but feel highly gratified by a recent and graceful compliment paid to their art and labours by an erudite, and in all other respects an expert and accomplished writer, who, in a critique published in the columns of the Daily Telegraph, accredits photography as the immediate resuscitator of a dying art, which in its zenith had transcended human forms and features with exactness and grace.

"Prior to the advent of photography" (so writes our correspondent in his dispatch) "British portraiture was more than dead. It was an unburied corpse, ghastly and repulsive. Portraiture in England had become a lost art, and in the art of producing representations of the human form divine we might have taken lessons from the war canoe dandies of New Zealand, or the pot-painters of the Celestial Empire. Two causes brought about the revival of the art. [Note.—Photography was the first.] The earliest Daguerreotypes of Claudet and Beard—flat, cloudy, ugly, and evanescent as they were—still from an artistic point of view were superior to the best average pictures exhibited at the Royal Academy as a portrait by Titians or Vandyke was superior to one by Miss LaCorey or Dicky Fitch. But when the Daguerreotype gave way to the Tablotype, when the magical wands of collodion and alumen were waved over plates and paper, and when the wonderful invention of photographic printing was developed, the doom of the conventional portrait was sealed, and the revolting thing became not only a monstrosity, but virtually an impossibility. In the face of the blessed sun, drawing so beautifully, distributing light and shade with such marvelous grace, rendering expression, atmosphere, substance, transparency, texture, with such astonishing fidelity, conventional portraiture could not but feel ashamed—could not but feel that henceforth it was no longer permissible to talk about such lies as had hitherto passed current."

Well done, honest critic! A veritable Daniel art thou in wisdom and in judgment; and with the courage of a Wilberforce thou hast bravely fought prejudice, error, and misapprehension. Thou mayest venture further, and tell the world that all portrait photographs are not "ordnance maps," or "microscopically objective charts."

I grant you, photography does not create expression; but faithfully it transcribes if taught of expression exists in the countenances of the original. If the works of A. Salomon, V. Blanchard, Robinson, the smaller productions of M. Crambey, together with those of the less celebrated and other talented photographers, be compared with examples of hand painting, it must be acknowledged that no painter, no engraver, ever succeeded in depicting more life-like and faithfully those mental characteristics which can be read by a glance at the faces of many of our eminent men. When features bear no impress of the mental light which hidden shines within, as in the case of Oliver Goldsmith, a portrait of such individual as painted by a Vandyke or Reynolds is much to be preferred to any camera production because the producer, by his skill, whilst preserving the likeness, impresses on it a reflex of the qualities of mind; and thus is the man as nature moulds him throughout, save that flesh becomes transparent and mind is seen in every feature. Rarely, however, has there been a more cunning hand at work than in producing these powers. More frequently has he to gratify, with an addition of naturally false gifts, courtly dotes, socially elevated misues, dukes, lords, baronets, snobocrats, and wealthy equires. These must be presented to posterity not as they appear in life, but with additions which to their wealth and station are best suited. Meaningless smirks, uncomfortably plain faces, receding foreheads, expressionless features, must be changed by the brush, which does what the camera cannot, inasmuch as it lyingly imparts to canvas a spuriously contrived semblance of intellect and dignity.

Where character exists, and the face of the possessor can show it, photography transcribes intellectual expression with inimitable fidelity; and the masters of photographic art are named, know full well how to control light, to arrange lines, to compose throughout with harmony and balance; in short, to accomplish everything that can be suggested by experience, artistic taste, and refined culture; and given intellectual models, and not inanimate living puppets on whom to exercise their skill, no painter's hand would succeed in producing more naturally and strikingly the leading characteristics of the persons that form the subject. All of these things are well when the faces have been registered, the power of paint rules supreme; but if a face is to be transcribed with its lines, its warts, and wrinkles added to whatever of mental power is indicated by the form
of each feature, photography can and does produce such works as which painters might after poch好转, but their skill would be at fault if the hand essayed imitation. I have at this moment in my mind's eye, portraits produced under the guidance of a Saloman and Blanchard, beautifully drawn marvellous faces, skilful distribution of light and shade, expression, substance, wondrous fidelity. Before such productions "conventional portrait" shows hideous, disgusting; on such, even the great masters of portrait painting, meek with involuntary admiration. Also! photographic triumphs end here; it is the apex of its capability, and should be acknowledged as the outer limit of its means of satisfying ambition. Photography has its mission—it transcribes more faithfully than human hand could do the work, and to a limited extent it interprets the wishes of the producer. But it does not, cannot, usurp the place occupied by the masters of hand-painting, because those can cause the workings of their minds to guide the brush or pencil which registers on blank canvas his thoughts as readily as an author describes imaginary scenes and characters with his pen, his ink, and his paper. Photography as a reproducer of hard facts should rigidly adhere to realities, and when it is seen that the follower of the art claim no more than legitimate due, the feelings of distrust which so long have blinded the judgment of art critics will slumber, and in their critiques on matters affecting our art they will ultimately adopt a just course, and thus will assist in raising the character and status of photography.

Photographs have sometimes ranked with impostures simply because photographers, unknown to themselves, are sometimes impostors, who delude themselves with ideas that their compositions class with high art, when, in the eyes of discerning observers, those productions intended to class as sublime are more nearly allied to the ludicrous. It is, however, an encouraging fact, that as years roll on, ambition is more and more prone to keep within sensible limits, and it is chiefly on that account that the claims of the art are admitted as genuine, because experts in art are not slow to perceive that photographers, as long as they keep within bounds, are fully entitled to praise, because of the aid they have given in enlarging the knowledge and technical skill of the painter. To have it admitted that the revival of the art of portrait painting is due to photography is an acknowledgment we have good reason to be proud of. As photographers, in their turn, they, and their art, will doubtless gain a position of which they need not, as now, be ashamed, when it is said, "Oh! he is only a photographer."

TOPOGRAPHICAL PHOTOGRAPHY.

BY D. WINSTANLEY.

Of the momentous changes which the steading hand of time effects slowly—very slowly, to be sure—but with a certain and completeness from which there is no appeal, many are of a kind of which in their various stages photography (to use an alliterative phrase) may make most masterly memoranda.

The pictures of ancient Liverpool, recently exhibited in that town, and, as I understand, now published by a local photographic firm, are of greater interest to others than those residing near the place, illustrating as they do the wonderful and complete changes effected in specific localities by the extension of civilised life. The site of St. George's Hall—a colossal modern pile, with ponderous cornices and massy columns—was but a little time ago the location of a rustic residence of the inter-timbered style characteristic of the architecture of a bygone age. Where we have now what may be described as a floating street leading to what before the fire was the finest landing-stage yet built, Messrs. Vandyke and Brown's reminiscence of the past shows it to have been a spot dedicated to the use of bathing vats.

And so, in the neighbourhood of every rising town, changes are going on which must at any rate be of interest to the local antiquarian, and which I would urge upon photographers to record, although the negatives of such subjects may frequently have little to recommend them from a pictorial point of view. The changes brought about by time, unaided by the hand of man, are, however, often so startling in their kind, that their photographic representation must inevitably prove of the very highest interest to those who follow after them.

No one, for instance, can visit the islands in the British Channel without being impressed profoundly with the changes that have made them as they are, and I cannot better illustrate the desirability of representing changing nature apart from her pictorial aspects, than by a reference to those interesting events which have separated Jersey from the Continent within historic times, and altered the coast of Brittany within the memory of living men.

From a work, "Les Mouvements de la Mer," it appears that "in the Gulf of Corduan, at the mouth of the Gironde, the sea has advanced 730 metres in eight-and-twenty years," and now flows more than ten yards deep over what a white age was but a sandy beach. The bay on whom is the site of the once flourishing city. When the tide is low, druidical remains, altars, monuments, may be observed beneath the waves, whilst groves of elms, as it is recorded, have been seen disposed with a regularity which shows a plantation once there was.

From the summit of Mont Orgueil Castle, near the town of Gorey, on the eastern coast of Jersey, may be seen today the mainland of Coutances (with its white cathedral spire), stretching in loneliness against the distant sky, and with many wide miles of water rolling in the space between.

From manuscripts and an ancient map in the monastery of Saint Michel, it appears that thirteen centuries ago the separation was effected by a rivulet bridged by a single plank, which the inhabitants were bound to keep in a condition of repair for the passage of the archdeacon of the church on his annual round.

The cause of these extraordinary changes are the effect in the sinking of the land, the reverse of which is taking place both north and south around the poles. About the coast of Brittany this subsidence is progressing at the rate of about two yards per hundred years. Should this continue for another thousand years, "the peninsula of Cotentin will become an island, and the ports of La Manche be destroyed," and in a period less than half as long as that during which the pyramids have braved the ravages of time, Paris itself will be engulfed beneath the Atlantic wave.

UTILISATION OF RESIDUES.—No. II.

BY PHOTO-CHEMICS.

We now come to the treatment of the development waste, and in connection with this part of our subject it is surprising how little photographers appear to know its value, and seem to consider it as a small quantity of silver, mixed up with a large amount of impurity and useless matter. This is really by no means the case.

The decompositions which ensue on the addition of iron to nitrate of silver are theoretically rather complicated, but for practical purposes it is sufficient to say that the precipitate in the process of developing consists of metallic silver in combination with iron. If this precipitate be collected and placed in a wide-mouthed bottle, and treated with diluted sulphuric acid till no more be dissolved, the residue when melted will consist of silver only.

FIXING SOLUTIONS.

The hypo or cyanide after use cannot have the silver separated by salt in the form of chloride, but we are com-
pelled to adopt another expedient, and precipitate it in the form of sulphide, by adding to the solution sulphide of potassium, or, as it is commonly called, liver of sulphur. There are one or two amusing facts in connexion with this process which are worth mentioning. The first is, that in America it has been made the subject of a patent. To show the utter absurdity of this, we may just mention that long before photography was even heard of, the use of sulphides for precipitating most of the metals was one of the simplest and best known facts in chemical analysis. The use of the same process in photography is nothing more than an application of non-photographiy known and logical research for separating the various metals into groups; and to show how absurd such a claim is, we may remark that if a photographer sent some old hyp to a chemist, and, without knowing what it was, asked him to separate the silver it contained, he would in the ordinary course do so by this means; while if the photographer did it himself, he would be liable to an action for infringing the patent. How our “cute” chemists can tolerate the exclusive working of a process which has long been public property is, as Artemus Ward would say, a “goat” of the richest character.

The next amusing point is, that on talking to a photographer lately as to the amount he received for his “plate,” when he came to his hyp residue he told us, “Oh, that’s worth a whole lot of money!” in the case of a photographer, because he makes less than a very little silver. Now, how does the matter actually stand? Reverting to our “combining numbers,” it will be seen that silver is 108, sulphur 16, so that, in fact, nearly seven-seighths of the weight of the precipitate formed on the addition of sulphide to old hyp consists of silver, or would do so but for the circumstance that some excess of sulphur is likewise deposited, which excess could easily be burnt off in an iron ladle, leaving the sulphide of silver nearly pure.

To those with a very little practical knowledge of chemical manipulation the conversion of this, together with the ashes from paper, &c., into nitrate of silver would be by no means difficult; but we think that this process could be better performed on a larger scale by the practical refiner. We have no wish to interfere with his legitimate business. We know that as a class they are men of probity and honour; but in their profession, as in other professions, there are many black sheep who take advantage of the ignorance of their clients, and fix their own value, from which there is no appeal or redress.

If those of our readers who are inexperienced in this matter can still be led to use quantities of coating paper for printing, and to this circumstance is, no doubt, due the fact of the increasing price of eggs, so that we are all of us on the look out for a substitute for albumenized paper. Every photographer would—especially if it obviated the many defects which such paper is liable to—be glad to meet with a substitute of this kind. We have not, however, got quite so far yet, and albumen may still have a long era before it; indeed, for years past the consumption of albumen in photography for one thing and another seems to have been on the increase.

To the photographer, therefore, it will be very handy to have albumen of uniform quality—as good as that from fresh eggs—in a dry state, ready to hand at any time, it being merely necessary to dissolve the dry material in a certain quantity of cold pure water. Such an albumen is now prepared commercially, the yolk, as well as all its good properties, being dried and preserved separately. The importance of this product cannot be valued too high, and its preparation is still surrounded by difficulties, owing to the easy decomposition of the egg-oil, as it is a question of preparing an article of food, and not merely a technical product. Eggs may be preserved in many ways unchanged in the shell, but must, of course, by reason of their fragile character, be well cared for.

The dry albumen is prepared both in sticks and in powder. It is easily dissolved in distilled or ordinary water; the solution is, however, in the first place turbid and full of flocculent matter, and requires to be beaten up and allowed to stand for some time, just like ordinary fresh white of egg, in order to clear it. When the liquid under the scum is poured off and diluted with water, for employment as a preliminary substratum for plates, and a drop or two of ammonia has been added, the albumen solution can be filtered perfectly clear with ease, even through good filter paper. In the latter case I have remarked that the filtering goes on much more rapidly if a uniform current of air is allowed to fall upon the liquid in the filter. In this way the solution is kept agitated, and the deposition of matter is prevented, and, consequently, the filter is not choked up; indeed, this is a good practice in all cases where it is difficult to filter. The funnel and filter-paper must, of course, be large enough for the purpose, so that any bubbles that are formed do not rise above the paper. The current of air may be arranged in several ways—for instance, by means of a gasometer, whose exit tube is connected with a glass tube that is allowed to dip down into the middle of the powder. The velocity of the air current is regulated by the tap. This method is only applicable to aqueous solutions, for such as are easily evaporated—collodion, for example—cannot be treated in this way.

If the albumen solution is filtered through wet sponge, or through linen, its clearness is by no means perfect, and strong solutions cannot, unfortunately, be treated in any other way. It is worthy of note that the dry albumen, if well preserved in and well dried, may be kept for a very long time, but solutions appear to become decomposed much sooner than that prepared from fresh albumen. As, however, a solution can be prepared at any time, the matter is of little importance.

It is easy to prepare the dry albumen itself, if such a course should appear desirable. Raw white of egg is beaten to a stiff froth, and then allowed to spontaneously in flat dishes at a temperature of 15° to 18° Resanum. It is necessary that the albumen should be well protected from dust or other particles falling upon it, and this is very well accomplished by the film of froth above becoming dry and hard. That a dry locality is necessary for the operation need scarcely be said. The glassy, brittle mass of dried albumen is very easily powdered. On dissolving the dry powder in water, it is necessary to see that it does not cake together, and it is well, therefore, to sprinkle the powder gently into the water while it is being stirred. The preparation of a solution is therefore rather a long operation.

Commercial albumen powder should be provided with a label, stating the amount of water necessary to produce a solution of the same consistency as fresh egg; this would be easy to calculate, the degree to which it must be diluted for the various purposes of the photographer.

Correspondence.

DEVENSHIRE SCENERY.

Sir,—I left off my last letter just as we had got down on the little pier that protects the crawlers and the base of the village of Clovally from the destructive effects of the N.W. gales. I forgot to say, that before I got there on the last occa-
sion, my assistant and I were nearly placed *hors de combat*. I mention it as a warning to any brother photographer who may be going that way on a similar errand. We were just driving down the Hobby, admiring the beauties of the peeps through the foliage, when our pony stumbled on a loose stone, and fell, pitching us both out of the trap with our outfits. A moment later, curiously enough, we found our chemicals, so severely shaken, that it in all probability spoiled several negatives that otherwise might have been good.

It will be seen that Clovelly Pier, built by Sir John Cary in the time of Richard II., of huge boulders, of the same character as are scattered on the beach, forms a picturesque object of itself. Three or four negatives can only fairly represent its peculiar character and construction. In 1850 a portion of it was extended after a terrible calamity happened to a score of fishing boats in the bay. A good general view from the pier, and also from the beach, with a wide-angle lens, should be taken, as it takes the whole village, and shows the peculiar character of the cottages rising one above another. Then one or more negatives should be taken of "Maseed Katie's Cottage," the favourite object for the artist, taking in the hills, the distant waterfall, and the sea. There is a sad history also connected with it, to which our postman poet, Cepem, has given expression, in a poem of touching sadness, under the above heading, and in the following lines:

"Under the cliff by the western shore,
Where the waters ever wander ever, wander
Looking for one she will never see more,
In the little cove down by the sea."

If Clovelly could be photographed from the sea, it would make the best picture. The street, both up and down, should be taken. It is only within the last few years that it has been supplied with as many like buildings. It was covered with the boulders of the beach, and woos beside him who was not well on his feet in wet weather! A view should be taken from Mount Pleasant, as it gives the character of the singular village. The church should be taken, both the exterior and interior (the latter I have not seen done), because it has some beautifully formed pillars. The Court House is always photographed, but as it is a modern building, erected on the old abbey burnt down, it has not much to commend it beyond being once the residence of the sole proprietor of the whole village.

After photographing these objects, you pass through grounds of the most lovely and picturesque character to Mouth Mill, a guide being supplied you. There are several noteworthy objects of which a picture or two should be secured, such as Wiggan Farm, Gower's Mill, Gallantry Bowe (which is a perpendicular rock, beautifully veined, three hundred feet in depth). This can easily be done from above, with the sea below. Mouth Mill is very interesting, and it has a remarkably large rock, severed by some confluence of nature from its fellows, with a cavern right through it, and is known as Black Church Rock. There are also the lime-kilns in sight, with the gurgling steam passing over its bed of boulders. Each and all can be made a good picture, and will repay the trouble of photographing.

I have by no means given all the interesting bits of Clovelly, but the objects mentioned, if well done, will sell commercially.

We pass on to Hartland, which is about six miles; but, as there is nothing of particular note in the village, we pass on to the old abbey, a sight that will amaze the strangest of old wise wise in their generation, for a more lovely valley could not be conceived for placing a monastery. Sheltered and deeply wooded on either side, with a trout stream meandering by, a path at the rear, where the deer wander, no wonder if they did sing:—

"Here would my willing soul stay,
If for its own sake it could be its last earthly lay.""}

There, however, is the Abbey, with the lofty church tower rising in the rear; and a splendid picture it makes. The building has been modernised. The cloisters of the old abbey form the basement of the eastern and western front, both of which should be taken. The church, which is near by, is well worth three or four negatives. It has a splendid lofty tower, and in the interior it has a very ancient screen. The church is dedicated to St. Nectan, and was famous at one time as containing the relics of that holy man. About a mile from this spot is Hartland Quay, where there is a fine opportunity to take in more sea views. The rocks here are grand, being both massive and precipitous, and are beautifully veined. A half dozen negatives taken would well repay the labour. A couple of miles further down is Hartland Point, well known both to ancient and modern seamen as a very dangerous promontory. The lighthouse now lifts its beacon of warning on it, and as the point has never been photographed, it would be doubly interesting to do so now. Between the Quay and the Point is also a magnificent waterfall, well worth a plate or two.

The principal reason why Hartland Point has not been photographed has been the difficulty of getting there; but this is now removed by going there by the Trinity Road to the lighthouse.

I have now done with this part of the coast, and next week I shall say something of Ilfracombe and Lynton.

Yours respectfully,

Theo Treade.

DEAR SIR,—I believe your readers will agree with me that a guide likely to prove of service to photographic tourists should be written in an unbiased and comprehensive manner, treating generally and fairly of the entire district of which it professes to speak, and not confined to a florid description of a small portion only, as this would be much like an advertisement for a particular hotel company. It would be useless to attempt giving a particular description of all the various objects of interest contained in an area of some two hundred square miles, as this would require more space than could be afforded in such a work as the *Photographic News*. A residence in this beautiful county of between thirty and forty years, principally in its Northern districts, enables me confidently to state that over the entire county are scattered objects of interest of almost every description worthy of the photographic tourist's notice; but provided his preference inclines to bold and rocky scenery, he will find this in its most sublime aspect in North Devon.

Great improvements have lately been made as to the convenience of transit, and to a London tourist there are now three lines of route open, each having its terminus at Ilfracombe, with branches to other places. The first would be from London to Exeter, thence to Barnstaple, thence to Ilfracombe per rail throughout. The next route is from London to Taunton, thence to Devon and Somerset, rail to Ilfracombe, saving distance and expense to the extent of forty miles. The third route would be from London to Taunton, thence to Minehead, thence per coach to Lynton, thence per brake to Ilfracombe. But should the tourist be a stout pedestrian, fond of wild moorland and river scenery, fishing, or peeping into out-of-the-way and secluded places, he can take the stage at Portlock, and diverge from the main line of route to Dulverton, or North Molton. Should he proceed direct he will reach Lynton and Lynmouth. The scenery of these places comprises rock, wood, and water, and in its own peculiar style rivals, if not excels, that of any other place in North Devon. The tourist having entered the district by its Eastern extremity, can proceed with the greatest facility through its whole length, stopping or diverging at various places as he pleases. Passing through Combemartin by the new road through Watermouth, whose giant caves are objects of great interest, the tourist will reach Ilfracombe, where accommodation can be procured suitable to any scale of expenditure. Conveyance by sea and land are readily obtainable by which to visit all parts of the district. As this town and neighbourhood are certainly most central and interesting positions of North Devon, I shall not be doing my duty either to them or the
tourist should I not give them something more than a mere passing notice; I will therefore do so in my next and concluding article.—Yours truly,

JAMES MARTIN.

PHOTOGRAPHING HORSES.

Dear Sir,—Will you allow me a space in your News as regards the photographing of horses? I will give a plan which I have used with every success. I got a man to shake some oats in a sieve, and got all the horse’s attention, then suddenly put the sieve behind his back. The horse will of course look for it, and in that moment take his photograph. I use one of Dallmeyer’s O.D.V. lenses (rapid), and enlarge after.—I remain, &c.,

C. R. P. VERNON.

EXPLOSIVE SILVER COMPOUNDS.

Dear Sir,—There was in the News a short time ago a warning against the use of ammonia or other alkali when boiling a silver bath, on the ground that the oxide of silver produced is explosive to a dangerous degree.

As I did not fear much mischief from the small amount of gas that could be liberated, I tried the experiment, using first washed oxide of silver thrown down by potass. A small quantity was placed wet on some filtering paper, and then over the hot part of a gas stove, the paper charred and smoldered away. The oxide of silver darkened in colour, but did not frighten anyone! Afterwards I tried some thrown out by ammonia, and not washed, drying it over a naked gas flame until the paper charred and took fire. In this case also there was nothing suggestive of the fifth of November.—Yours truly,

Ed. Serlet.

Talk in the Studio.

PRECIPITATION OF SILVER BY PROTOXIDE OF URAMIUM.—M. Isambert, writing on this subject in the Comptes Rendus, says:—When metallic oxides act upon solutions of silver salts, the latter commonly combine in the precipitation of the silver oxide, but there may be produced in some cases a deposit of metallic silver. Ebelmen has shown that protoxide of uranium produces in solutions of nitrate of silver a deposit of metal exactly as does copper, one equivalent of uranium replacing one equivalent of silver, without escape of gas. On repeating Ebelmen’s experiment, the author finds the final result completely exact. Protoxide of uranium being thrown into a very neutral solution of nitrate of silver, and well stirred, a bulk of protoxide is formed, whilst the protoxide dissolved, and the liquid becomes green. On continuing to stir, this colour disappears, and is succeeded by a yellow shade, characteristic of the sesqui salts of uranium. At the same time, the precipitate decreases in bulk and changes its appearance, passing from its original state of oxygen to that of metallic silver. Hence protoxide of iron, in like manner, produces a precipitate of metallic silver, with formation of sesquioxide of iron. This property of protoxides, of passing to a higher state of oxidation, and of throwing down metallic silver, is shared by their salts.—Chemical News.

Mrs. Partington, visiting a photographic gallery recently, asked the proprietor the names of the different style pictures, and was politely informed that they were the “Rembrandts,” “Berlin Heads,” “Embosed Cameo Vignettes,” “Medallion Cartes,” “Romance Black and White,” “Victoria and cabinet,” &c. Mrs. Partington called Ike (who was looking at a stereo view upright) up to the show cases, and pointing to them in the same manner that the photographer did, informed Ike “that’s the sunburnt style, that’s burning heads, that’s Boss camilla vignette’s, no smudging on it, that’s the victoria and cabinet, that’s the victoria cartes, and that’s the cabinet and showworth. I shouldn’t wonder if the next unfailing style will be the vinagrete again?” added Mrs. P., looking over her spec. at the photographer. “I should not wonder at all—you are fond of pictures, I perceive, madam.” Yes, but then I am one of the amateur sort, but still I am partially fond of pictures of exquisites personages.—Written in a Photographic News.

A SILVERING POWDER for coating copper consists of nitrate of silver 30 grains, common salt 50 grains, cream of tartar 34 drachms. Mix, molition with water, and apply.

IGNORAMUS has deprived us of the opportunity of giving him any information or advice, by great carelessness or lack of knowledge in the packing of his negatives which reached us in a hundred fragments. A piece of tape placed behind a piece of board without edges or packing of any kind to keep off the pressure, must inevitably be cracked or broken up into fragments, however carefully treated in transit: each blow or the stamp, adding the rate, post card, &c., would produce a fresh fracture. The issue is that our correspondent, by taking insufficient care, has wasted the care expended, and is disappointed of the answer for which he wished, and we have our writing table covered with dangerous minute fragments and spicula of glass, falling out, despite care in unpacking the parcel. To travel safety, negatives or plates of glass must be placed in a box, or its equivalent. If the boxes used here had had narrow strips of wood glued or fastened with brass all round the edges of one of the boards, to form a cell or box, and the negative, folded in a piece of wadding, or cloth, or flannel, placed therein, it would have travelled with perfect safety. “Ignoramus” does not say what the nature of the defect is. Let him describe it, and send us a print from a defective negative. We may then possibly be able to satisfy him.

STUDIO.—We prefer No. 1, which will permit more effective light to reach the sitter. You will find the west a troublesome aspect, we fear, for portraiture, as you will be troubled with direct sunlight during the greater part of the day. But I will probably be most effectual, and most easy to work. You will probably find a large movable screen covered with tracing cloth or tissue-paper useful in breaking the direct sunlight falling on the sitter, without seriously destroying the illumination.

T. J. ACR.—It is impossible to give special advice for general cases. Almost everything depends upon the size and shape of the interior, how they are illuminated, and many other conditions. It is necessary to meet which practical judgment and experience applied on the spot are imperative. If the circumstances admit, a portrait lens with small central stops may be used. In other cases a single lens, with the stop in front placed variable. You will find an article on p. 82 of our Year-Book for 1877, that furnishes many very useful practical hints on photographing interiors.

SOUTHERN HEMISPHERE.—P.O. order received, and handed to our Publisher, who will attend to your business instructions. Of the lenses that you mark, B will answer best. The general character of your studio appears to be very good. There is nothing better than starch as a permanent means of obstructing the direct rays of the sun without losing much light, as it gives a thin, delicate translucent film; is easily applied; does not soon soil, and is easily removed when necessary. Ebelmen’s results are necessarily of a varied character, and require various varieties of lighting. The principle is that in all cases to admit a strong direct light through a narrow aperture, and to have means of securing reflected lights in position by the use of movable screens. There is no one best formula for portraits or landscapes, as all formulae require at times modifying to suit conditions. The ordinary recognized formula is the best one, and we have published hundreds of times. You can scarcely suppose that we have kept unpublished the best formula, in order to impart it in an answer in this column. To intensify with chlorite of gold, apply the ordinary toning bath used for nitrate to the fixed and washed negative. A strong solution of chlorite of gold will work quicker.

K Y B E R.—It is possible that the plan of making blinds which you propose may answer; but we are not sufficiently familiar with it to recommend it. We have however a large number of lights for the top light, blinds on spring rollers placed at the ridge; and for the side light, curtains sliding on rods. The character of carpet for the floor of studio is not of a matter of taste. It should not be too large or pronounced in pattern. Any quiet neutral tint you may prefer will answer for interior of studio. You should never mix up advertising matters or business concerns of any kind with questions addressed to the Editor, as it causes much delay, and the latter to the different departments for attention to different portions.

JOHN T. GLOVER.—We hope shortly to be able to publish more particulars of Mr. Vander Weide’s electric system of lighting. Thanks for the interesting facts you communicate.

CAPTAIN TURTON.—Thanks. Will be duly acknowledged in next list of subscriptions. Either of our English correspondents will supply the information.

TO ADVERTISERS.—Owing to the pressure on our advertising space the Publishers beg the notice that advertisements are compelled to hold over for the next issues.

Several Correspondents in your next.
PHOTOGRAPHY IN AND OUT OF THE STUDIO.

SUMMER TOURS.

It is a mistake to put off one’s summer outing till late in the year. We know very well it is fashionable to do that, that the weather is cooler then than in June; and that summer works such charms upon the foliage as to render the landscape tints more bright and varied than is the case when mere masses of green hang from the boughs, and clothe the country with verdant tapestry. There are the autumn fruits to be enjoyed, and wonderful sunsets to be seen, and a hundred and one other advantages of autumn; but, for all that, we recommend an early holiday, especially to the tourist or traveller going abroad. Photographic apparatus can now-a-days be packed away within such trifling limits, that certainly amateurs have little need to trouble about it, and may go anywhere in the country without feeling inconvenienced thereby. There is no reason why they cannot avail themselves of all the advantages that ordinary tourists enjoy, for their companions in travelling is very often far less than one sees the fashionable tourist with. A camera, box of dry plates, and even dark tent and chemicals, do not together make up the amount of baggage that some of “Cook’s tourists” are wont to carry with them, for it would be a bulky equipment indeed that would not go within the space of an ordinary sized portmanteau, and perhaps not only not fill it, but leave a good deal of room for more valuable articles. Many take a cloche coat and silk waistcoat with them to appear in at the grand hotels at Interlaken and Baden-Baden, for, in some of these fine hostels, it is almost de rigueur to appear in a dress suit at table d’hote. A man in Scotch tweeds or knickerbockers will soon become a rarity in those civilised regions, and a mountain tour will henceforth involve not only boots and suits of flannel, but a supply of dress shirts, white ties, and laced-up shoes. If you do not come accompanied by trunks and portmanteaus, you are looked upon coldly by the grand maître d’hôtel and his satellites, and so replete are they with custom that in le gros de la saison, as our French neighbours aptly express it, a modest traveller with a knapsack must pray to be taken in. It is not a question then of getting bed and supper at a moderate rate, but to get one at any cost, and the exorbitant sums demanded, and of course obtained by hotel proprietors, frequently cripples one’s finances, so much so, perhaps, as to compel you to shorten your tour, or forego it the succeeding year. In the season, in Switzerland, the prices rise with the demand. Point d’argent, point de Suisse, is a saying most people have heard, and many know the meaning of. On the Rhine, at the German Spas, in Scotland, the English lakes, or wherever you turn, matters are no better in the usual holiday time, and this is one of the main reasons why we advise those who can to take their holiday early. Although the photographer may lose some effects by not waiting for the autumn, he is not so trammeled as the painter, and the changing undergrowth in woods and dells, the ferns and forest flowers, are as pretty in June as they are three months later. Then there are such glorious long days about this time of the year, which must certainly not be forgotten on the side of summer, and if the traveller should be troubled with a few very hot mornings he must remember that in September and October one is apt also to be unfortunate, and to come in for a slice of dull November weather, or cold winter rain, as being the red leaves down in shoes, and sudden the ground for four days together. In early summer he is comparatively undisturbed by other tourists; he does not find the inns and hotels filled to overflowing, but the landlord is glad to have him, and looks after him with care and attention, such as he could not secure later for love or money. When he visits this place or that, he does not find nature spoilt by crowds of visitors, giving an air of cockneyism to everything he sees, and this freedom from groups of tourists is one of all others which the landscape photographer desires.

Robinson, in his work on “Pictorial Effect in Photography,” has pointed out how a pretty rustic landscape may be altogether spoilt by the introduction into it of a portrait unsuited to the scene—a finely dressed dandy in a country lane, for instance—and many of our readers may have seen the poor artists at Botwe get badgered by their clients, in all sorts of costumes, who take up positions in the Fairy Glen on the Conway, straight in front of the painters’ canvasses. It is generally considered a very funny thing on the part of tourists to plague a painter or photographer when earnestly at work, and the latter is especially at their mercy, for with him the picture depends upon securing a few moments’ favourable lighting after he has drawn the slide. Thus both a saving of worry and anxiety, as also of money, is generally effected by those who travel in early summer, and as everybody takes an outing now-a-days, and wants to be as fashionable as he can, quitting town at the right moment, when Parliament is up, and coming back again just when the theatres and the winter exhibitions are commencing, it follows as a matter of course that hotels and tourist districts are full to the very top during this brief period. In June you may go to the most charming spots on the Lake of Lucerne in the Engadine, on Windermere, in North Wales, or on Loch Lomond, and make arrangements to stop a week or ten days at a comfortable hotel for a moderate amount, while later on not only will they refuse to listen to any bargain you desire to make during your stay, but you may consider yourself fortunate to get taken in under any circumstances at all. One more hint to those going abroad. Travellers who can speak the language of the country they are visiting, or at any rate, are sufficiently familiar with it to get on somehow, have, of course, great advantages over those who must perform trust themselves to Cook, or Gaze, or other of the excursion agents. It is a good plan when you have fixed on your route, and calculated the expense of travel you have to meet, to consult the “circular tours” which almost every foreign railway issues tickets for in summer. Cook’s Excursionist contains a number of these “circular tour tickets,” which oftimes may be used to advantage; in like manner every railway company pretty well, in France, Germany, Switzerland, &c., have their own tours. Head to each photographic, the German Excursionist contains several closely printed pages of these tours, and when an intending tourist has sketched out his route, it is very likely he can get one of these plans to suit him, in which case he may take a ticket at a very reduced rate. We will give one illustration of this. Supposing you desire to visit the Pyrenees; you go to Paris, and then find that a second-class ticket to Bayonne will cost you between two or three pounds; then come sundry railway fares to help you on your way across the mountain range—say, as far as Toulouse—and then the journey back to Paris. In this way the cost of the railway journey from Paris to the Pyrenees and back would amount at least to seven pounds; and yet a circular ticket, first-class, out and home, which you can use or not, just as you like, when you get among the Pyrenees, can be had in Paris, for five pounds, which would not take you there and back third-class. So from Cologne, from Frankfort, from Berlin, and from scores of other places, circular tickets are issued through interesting districts, and those of our readers who are meditating a foreign tour this summer will do well, therefore, to study these before making definite arrangements.

A NEW DRY PROCESS.

Mr. Carey Lea gives, in the Scientific American, the following details of his most recent modification of the emulsion process, of which he appears to think very highly. He says:—
The method gives, by simply pouring an emulsion over glass, not only a high, but I may say an intense, sensitiveness. Moreover, by virtue of the silver iodide which they contain, these plates need no backing. They develop with great rapidity, and need no intensifying, so that the whole operation, from first to last, is reduced to the most absolute simplicity. The advantages in the way of facility of management and the high degree of sensitiveness are such that I should not be surprised to see these dry plates largely supersede the wet plates. In fact, a beginner will more easily work this dry method than the wet. When the emulsion is to be obtained commercially, which it soon will be, as I do not propose to place any restriction upon its manufacture by any one who may choose to prepare it.

Collodion.—To each ounce of solvent, consisting of alcohol and ether in equal parts, take ordinary crystalized cadmium bromide, six, and a-half grains; ammonium bromide, two grains; ammonium iodide, one and a-half grains; cupric chloride, one and a-half grains. About eight grains of intense pyroxylone to the ounce, with two drops of aqua regia. Saturate with silver nitrate, using from twenty to twenty-five grains to the ounce. The first-mentioned quantity is excellent for ordinary work; when a very high degree of sensitiveness is desired, the larger quantity may be used. For the reason that the emulsion is to be dried, some economy may be practised by making a more concentrated emulsion, as follows:—

Ordinary cadmium bromide ... 9 grains
Ammonium bromide ... 2
Ammonium iodide ... 2
Cupric chloride ... 2

Use about ten grains of intense pyroxylone. The silver nitrate must be increased in the same proportion as the silver iodide is diminished, in order to maintain the strength of the collodion. Three ounces of this collodion will, after treatment, give four ounces of finished emulsion.

The best results are obtained by keeping this emulsion, with occasional shaking, for from twenty-four to thirty-six hours. It is then to be poured out into a flat dish and allowed to set. Particular care is needed in this part of the operation; the preservative must be applied just at the right time—neither too soon nor too long after the pouring out. The emulsion must be occasionally examined, and moved about in the dish to promote equal drying. As soon as a skin forms on it, holes must be made through it, and the collodion underneath made to flow out and over it. If this be neglected, the surface will become hard and leathery, while the bottom is soft. The object is to keep the whole mass as nearly uniform as possible, and, as soon as it is gelatinous, to apply the next treatment. The proper condition can be judged of by touching with the tip of the finger; as soon as nothing comes off upon the finger, the emulsion is ready for the preservative.

Any preservative may be used. As to the effects of different preservatives, I will speak presently. If the last quantity of silver be used, the preservative may actually be applied in its ordinary condition; but if the larger, then it will be well to add to the preservative one-tenth of its bulk of ordinary acetic acid (No. 8 or Beaufoy’s).

The preservative is to be poured into the dish, and then immediately the film is to be plunged up with a porcelain, horn, or glass spatula (not a metallic one), and reduced to flat places; and the whole, presented in a film, is to be transferred into a convenient glass jar—not too small. The flakes of emulsion are to be occasionally stirred, and left in contact with the preservative for fifteen minutes from the time when it was first poured over the mass. (In operating upon a large scale, commercially, it will probably be found better to leave a little longer in contact with the preservative, and always to acidify. For working with a few ounces, the foregoing is the right way.) The preservative is then poured off, and water poured on, the flakes well stirred up, and the water changed several times. The flakes are then left to stand under clean water for about an hour; then several more changes, then stand another hour; then several more changes. By this time everything soluble is extracted from the flakes; indeed, after the first hour no silver can be found in the wash water. We have now only to dry. This may be done at ordinary temperatures, or the vessel may be set over a stove, provided its bottom be not allowed to become hotter than the hand can bear. The vessels must be thoroughly; the flakes are wonderfuly, and curl up like tea leaves. They are not white, but of a medium grey colour, notwithstanding which they make a pure cream-coloured emulsion.

To re-emulsify, the dried flakes are put into a bottle, and are covered with one-third ether, one-third alcohol, and one-third plain collodion. They must be well shaken at intervals. The new emulsion is not in good order till after at least forty-eight hours, and is better at the end of a week. When it has once been thoroughly mixed with the liquids, and has been shaken at intervals for some days, it seems to lose all disposition to settle, and makes a most excellent emulsion. There is no reason why it should not keep indefinitely. Or it may be preserved in the dry state, and emulsified at any moment, by pouring twenty to twenty-five grains of the dry emulsion to each ounce of solvents. Three- and-a-quarter ounces of collodion, formula No. 2, will yield about one hundred grains of dry flakes.

Preservatives.—The character of the image will depend very much upon the preservative used.

Albumen Preservative.—This gives an exceedingly sensitive and delicate plate, with much less density than most of the other preparations. For this reason I prefer it to the rest, as tending to give detail in both lights and shadows, with great variety of half-tone. My formula is—

Water ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... 12 ounces
Thick gum and sugar solution ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... 1 ounce
Prepared albumen ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... 1 pound
Sixty-grain alcoholic solution gallic acid 1
Sixty-grain tannin solution (in water) ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... 1

To be added in the order named. If rather more density be required, double the tannin. I use it as above. This preservative works very cleanly and satisfactorily. I use it exclusively.

Gallic Acid and Coffee.—A mixture of gallic acid and coffee, using about two ounces of sixty-grain solution to twelve ounces of infusion of roasted coffee, gives very good results; it should, however, be acidified with acetic acid, using about half-an-ounce of Beaufoy’s (No. 8) to the above quantity. It gives a blacker image than No. 1, and more intensity. It will probably be useful when the pyroxylone is deficient in inert aty. It gives excellent transparentities by exposure under a negative, but too intense for lantern work, for which No. 1 is much better, as well as for negatives.

Development.—For a 1/4 by 1/4 plate pour four ounces of water into a 7 by 9 dish, add half a drachm of sixty-grain solution of pyrogallic acid in alcohol, and put in the plate. Mix in a bottle equal quantities of a fifteen-grain solution of potassium bromide and an eighty-grain ammonium carbonate. Of this mixture pour one fluid drachm into the dish. When the detail appears, add another drachm, and later, if necessary, a third; or add half a drachm of the ammonium carbonate solution without bromide. The two first additions must have bromide; the third is best without for a negative—best with for a transparency. Fix in the hypophosphite solution of the same strength as used for wet plates.

I should have mentioned that I always keep the colloidion for a month—for several, if possible. The plates should be edged with a solution of india-rubber in benzole.
The principle of applying a preservative to a mass of material at once, and then washing it out again, could be patented. This is common to the new processes. The plan of applying a silver bath to a mass of partially dried collodion is also new and patentable. Convinced as I am of the very great usefulness of these processes, I believe that such patents would be very valuable. I prefer, however, to give them freely to any one caring to use them, asking only, in return, to have them ascribed to their author, and not appropriated by those who may make trivial modifications on them.

PRACTICAL PORTRAIT PHOTOGRAPHY.

BY WILLIAM HEIGHWAY.

CHAPTER VII.

REDEVELOPMENT, AND INTENSIFICATION.—THE FIXING SOLUTIONS—VARNISHING.

Redevelopment and Intensification are corrective measures; properly lighted, exposed, and developed, the negative should not require either of these manipulations to produce the required effect. The difference between these two methods may be thus described. Redevelopment is a second application of developer, or a solution of pyrogallic acid and silver, before the negative is fixed, for the purpose of bringing out further detail, which the developer has failed to do; while intensifying or "strengthening" is the application of the pyrogallic acid solution and silver to any extent, after fixing the negative, tending only to strengthen the image already formed on the plate, and having no effect in bringing out any further detail.

As I have said before, these methods should not be resorted to unless, from some cause, you are unable to get sufficient time of exposure on the plate, as in the case of a child or nervous sitter, or from the weakness of the light. With your bath and collodion in proper working order the negative should grow under development to a perfect density. If your negatives come up uniformly weak and thin, and you know the lighting is good, and have confidence in your sensitizing solution, weaken the developer a little with water, adding a drop or two of acid.

In the case of a negative being too thin or weak—that is, lacking sufficient contrast between the lights and shadows—it may be strengthened in various ways, either before or after it is "fixed."

If it is found necessary to strengthen before fixing, the negative should be thoroughly washed, and flowed with a small quantity of a solution of

Pyrogallic acid ... ... 40 grains
Citric acid... ... 40
Water ... ... 30 ounces

Pour a little of this solution into a small glass or graduate similar to that used for the development; pour the solution over the plate two or three times, covering it in every part, draining it back into the glass, not to waste it; to this add a few drops of 20-grain solution of silver (in water), and with this flow the plate until the desired density is gained, or the solution turns "muddy."

If it is not sufficient to strengthen the negative, great care must be taken to thoroughly wash off the hypo-sulfite of soda, as its presence causes bluish stains and streaks. This carefully done, proceed to strengthen with pyrogallic acid and silver, using the pre-
cautions before described against streaks. This operation of strengthening after fixing the negative has the tendency to change the colour of the film to a bluish hue, but the colour better adapted to printing purposes, of an olive brown, may be restored by placing the negative again in the hypo-sulfite of soda solution after thoroughly washing off the intensifier. Thoroughly wash away all traces of hypo-sulfite of soda.

While the process of redevelopment or strengthening before fixation of the negative must be conducted in non-
actinic light, and before the negative has been so exposed after development, because actinic light has still an influence on the iodide of silver, it is not absolutely necessary with the intensification of the fixed image, a weak diffused light not affecting the deposit of silver.

When the negative is of a subject white and black, as copies of engravings, printed matter, manuscripts, &c., sulphuret of potassium or bichloride of mercury and ammonia are used as intensifying agents. Permanganate of potassium, tincture of iodine, &c., are also sometimes used as intensifiers.

To Strengthen with Sulphuret of Potassium.—Strengthen the negative before fixing as before described with Pyrogallic acid; fix and wash the negative thoroughly. This will not be sufficient, as you want the whites of the negative perfectly opaque. Take in your developing glass a piece of sulphuret of potassium of the size of a common marble, filling the glass with water; and, without waiting for it to dissolve, flow it over the plate; continue this, the solution gaining strength as the sulphuret dissolves. The plate was now gradually assumed a purplish black hue until the required intensity is gained. The reason why the sulphuret is not allowed to fully dissolve before beginning the intensification is, that its action would be too rapid to allow the operator to flow the plate without causing streaks and stains.

The objections to the use of sulphuret of potassium are so strong, almost to nullify its virtues as an agent for intensification. In the first place, negatives strengthened by it cannot be kept in a state of preservation long, owing to the decomposition of the sulphuret of silver which is formed in the film; secondly, it can only be prepared in solution at the very moment of use; and thirdly, the smell of sulphuret of potassium is so offensive that some operators will use it at all. For these reasons, you will say, They certainly are; but still the sulphuret is at times very useful as a rapid and sure intensifier.

To Intensify with Bichloride of Mercury and Ammonia.—Strengthen the negative with pyrogallic acid and silver as before described, wash, and fix, and again treat it to a thorough washing. Now flow the plate with a saturated solution of mercury in water, 1 part to 6 parts of water. (When a liquid has dissolved as much of a solid as it is capable of doing, it is termed a saturated solution. Therefore you will understand by a saturated solution of bichloride of mercury that the water in which the bichloride of mercury was dissolved has taken up as much as it was capable of doing.) Continue to flow this solution on and off the plate till the image, first turning to a greyish white and gradually growing more pure and uniformly white. Wash the plate, and flow on a weak solution of ammonia 1 part and water 8 parts. Gradually and cautiously increase the strength of this solution by adding ammonia. The plate will now darken until it grows perfectly opaque and black.

The New and Simple Method of Recovering Silver from Hypo-sulfite Wastes.

BY JAMES CHISHOLM.

In the Bulletin for April, 1874, I communicated a short method of recovering silver from hypo-sulfite of soda.
SULPHOCYANIDE FOR FIXING.

HYPOSULPHITE of soda has been at once one of the greatest boons and the greatest banes ever introduced into photography. If hyposulphite of soda as a solvent of silver salts had been known earlier, it is probable that photography as a practical art would have been removed, three or four months older than it is now. Sun pictures, as is well known, were produced at the commencement of the present century, but, for want of the knowledge of a fixer agent, no enduring results followed the early experiments. In the earliest works of Talbot and Daguerre, the fixers employed were very imperfect. Daguerre if we remember it was a soluble salt of common salt, whilst Fox Talbot used bromide of potassium. Sir John Herschel's introduction of hyposulphite of soda at once banished all other imperfect solvents of silver salts, and became recognized as the fixer agent, *par excellence*, a position which it has maintained to this day. It has been the subject of almost unlimited obloquy and denunciation, but it has never been superseded.

The avowed object of Mr. Hooper's paper, read at the meeting of the Photographic Society on Tuesday evening, was to aid in superseding it by the use of sulphocyanides as fixing agents. In answer to a challenge as to his own practical experience in the use of the sulphocyanides, he distinctly avowed that his aim was rather to stimulate experiment and enquiry than to state his own limited experience. The evidence he had collected from the statements of the gentlemen who a dozen years ago urged the use of sulphocyanides in fixing seemed most satisfactory and conclusive as to their superiority to hyposulphite of soda. It only required to be manufactured in a larger scale and at a cheaper rate to meet every desire of photographers. Mr. Spiller followed, and in a brief paper pointed out the advantage of using it as a by-product from gas liquor at a cheap rate, so that, instead of paying three or four shillings per pound, it might be produced to sell at three or four pence per pound. With somewhat of caution and hesitation, he said, in answer to the President, that, though he thought it was a better fixing agent than hyposulphite of soda; but he had not had much practical experience in its use. The call for the results of practical experience, responses were poured in on the night, none of which was, unfortunately, met with any response, and no practical information was forthcoming. We can, however, to some extent supply the omission.
